Abstract

The estrogen receptor alpha (ERα) plays a critical role in the pathogenesis and clinical behavior of breast cancer. To obtain further insights into the molecular basis of estrogen-dependent forms of this malignancy, we used real-time quantitative reverse transcription (RT)-PCR to compare the mRNA expression of 560 selected genes in ERα-positive and ERα-negative breast tumors. Fifty-one (9.1%) of the 560 genes were significantly upregulated in ERα-positive breast tumors compared with ERα-negative breast tumors. In addition to well-known ERα-induced genes (PGR, TFF1/PS2, BCL2, ERBB4, CCND1, etc.) and genes recently identified by cDNA microarray-based approaches (GATA3, TFF3, MYB, STC2, HPN/HEPSIN, FOXA1, XBP1, SLC39A6/LIV-1, etc.), an appreciable number of novel genes were identified, many of which were weakly expressed. This validates the use of large-scale real-time RT-PCR as a method complementary to cDNA microarrays for molecular tumor profiling. Most of the new genes identified here encoded secreted proteins (SEMA3B and CLU), growth factors (BDNF, FGF2 and EGF), growth factor receptors (IL6ST, PTPRT, RET, VEGFR1 and FGRFR2) or metabolic enzymes (CYP2B6, CA12, ACADSB, NAT1, LRBA, SLC7A2 and SULT2B1). Importantly, we also identified a large number of genes encoding proteins with either pro-apoptotic (PUMA, NOXA and TATP7) or anti-apoptotic properties (BCL2, DNTP73 and TRAILR3). Surprisingly, only a small proportion of the 51 genes identified in breast tumor biopsy specimens were confirmed to be ERα-regulated and/or E2-regulated in vitro (cultured cell lines). Therefore, this study identified a limited number of genes and signaling pathways, which better delineate the role of ERα in breast cancer. Some of the genes identified here could be useful for diagnosis or for predicting endocrine responsiveness, and could form the basis for novel therapeutic strategies.

Endocrine-Related Cancer (2006) 13 1109–1120

Introduction

Estrogens are important regulators of growth and differentiation in the normal mammary gland, and also play a major role in the onset and progression of breast cancer (Pike et al. 1993). Estrogens act via their receptors (estrogen receptors; ERs), which belong to the nuclear receptor superfamily of ligand-activated transcription factors that control physiological and pathological processes, largely by regulating gene transcription (McDonnell & Norris 2002).

The mitogenic effects of estrogens are largely attributed to their ability to increase the expression of key cell-cycle regulatory genes (Prall et al. 1997). However, regulation of cell proliferation is only one...
aspect of estrogen action, and there is a pressing need to identify the full set of estrogen-responsive genes. The existence of other ER signaling pathways that are independent of estrogen has also been postulated (Zwijsen et al. 1998, Ding et al. 2003). Thus, to investigate the full range of ER signaling, gene expression profiling studies should compare ER+ and ER− tumors rather than focus solely on ERα-positive breast tumor cell lines, regulated or not by estrogens (MCF7, T-47D, etc.), which may not accurately reflect the physiological and pathological effects of ER signaling in vivo.

The recent advent of efficient tools for large-scale gene expression analysis has already provided new insights into the involvement of gene networks and regulatory pathways in various tumor processes (DeRisi et al. 1996). cDNA microarrays can be used to test the expression of thousands of genes at a time, while real-time RT-PCR offers more accurate and quantitative information on smaller numbers of selected candidate genes (Latil et al. 2003, Bieche et al. 2004a).

Here, to identify new estrogen-responsive (or estrogen receptor-responsive) genes, we used real-time RT-PCR to quantify the mRNA expression of a large number of selected genes in pooled ERα-positive breast tumors, in comparison with pooled ERα-negative breast tumors (screening set). Thus we determined the expression level of 560 genes known to be involved in various cellular and molecular mechanisms associated with tumorigenesis. We particularly focused on the expression of genes found, by means of microarray analysis of breast tumor biopsies, to co-cluster with ERα, such as TFF3, GATA3, FOXA1/HNF3A, SLC39A6/LIV-1, XBP1, STC2, HPN/HEPSIN and MYB (Perou et al. 2000, Gruvberger et al. 2001, Sorlie et al. 2001, West et al. 2001, Bertucci et al. 2002, van’t Veer et al. 2002).

Genes of interest were further investigated in an independent well-characterized series of 36 individual breast tumor samples, including 24 ERα-positive and 12 ERα-negative samples (validation set), as well as in five breast tumor cell lines and in the MCF7 cell line treated with E2.

Twelve tumors (six ERα-positive and six ERα-negative breast tumors) were used for the initial pooled sample analysis (screening set).

Thirty-six tumors constituted the validation set: all originated from two previous published studies (Bieche et al. 2001a, 2001b) and were selected so that two-third (24) were ERα-positive, whereas the remaining 12 were ERα-negative.

The 36 patients from the validation set met the following criteria: primary unilateral non-metastatic breast carcinoma; complete clinical, histological, and biological information available; no radiotherapy or chemotherapy before surgery; and full follow-up at Centre René Huguenin.

Patients underwent physical examinations and routine chest radiography every 3 months for 2 years and then annually. Mammograms were also done annually. Estrogen receptor status was determined at the protein level by biochemical enzymatic immuno-assay (EIA) method and confirmed by ERα real-time quantitative RT-PCR assay (Bieche et al. 2001c). The mRNA level median of ERα gene was 1 (range, 0.2–5.1) in the ERα-negative breast tumor group and 711 (range, 70.8–1938) in the ERα-positive breast tumor group.

All the 24 ERα-positive breast tumor patients received post-operative adjuvant endocrine therapy (tamoxifen, 20 mg daily for 3–5 years), and no other treatment. The median follow-up was 7.3 years (range 3.2–12.5 years). Twelve of the 24 ERα-positive breast tumor patients relapsed.

The tumor samples were flash-frozen in liquid nitrogen and stored at −80 °C until RNA extraction.

We also analyzed five breast tumor cell lines obtained from the American Type Culture Collection (ATCC), including two ERα-positive cell lines (MCF7 and T-47D) and 3 REα-negative cell lines (MDA-MB-231, MDA-MB-435 and SK-BR-3).

**MCF7 cell line treated with E2**

Prior to treatment, MCF7 cells were purged for four days in Dulbecco’s Modified Eagle Medium without phenol red supplemented with 3% of steroid-depleted, dextran-coated charcoal-treated fetal calf serum. Cells were then treated for 4 days (with one media change) under the following pharmacological conditions: steroid-depleted medium (vehicle) and 1nM E2 (17β-estradiol).

**Real-time RT-PCR**

*Theoretical basis*

Reactions are characterized by the point during cycling when amplification of the PCR product is first detected,

**Materials and methods**

**Patients and samples**

We analyzed tissue samples from primary breast tumors excised from 48 women at Centre René Huguenin. Tumor samples containing more than 70% of tumor cells were considered suitable for the study.
rather than the amount of PCR product accumulated after a fixed number of cycles. The larger the starting quantity of the target molecule, the earlier a significant increase in fluorescence will be observed. The parameter \( C_T \) (threshold cycle) is defined as the fractional cycle number at which the fluorescence generated by cleavage of a TaqMan probe (or by SYBR green dye–amplicon complex formation) passes a fixed threshold above baseline. The increase in fluorescent signal associated with exponential growth of PCR products is detected by the laser detector of the ABI Prism 7700 Sequence Detection System (Perkin–Elmer Applied Biosystems, Foster City, CA, USA), using PE Biosystems analysis software according to the manufacturer’s manuals.

The precise amount of total RNA added to each reaction mix (based on optical density) and its quality (i.e., lack of extensive degradation) are both difficult to assess. Therefore, we also quantified transcripts of two endogenous RNA control genes involved in two cellular metabolic pathways, namely TBP (Genbank accession NM_003194), which encodes the TATA box-binding protein (a component of the DNA-binding protein complex TFIID), and RPLP0 (also known as 36B4; NM_001002), which encodes human acidic ribosomal phosphoprotein P0. Each sample was normalized on the basis of its TBP (or RPLP0) content.

Results, expressed as \( N_{\text{target}} \)-fold differences in target gene expression relative to the TBP (or RPLP0) gene, and termed ‘\( N_{\text{target}} \)’, were determined as

\[
N_{\text{target}} = 2^{\Delta C_{T, \text{sample}}}
\]

where the \( \Delta C_{T} \) value of the sample was determined by subtracting the average \( C_{T} \) value of the target gene from the average \( C_{T} \) value of the TBP (or RPLP0) gene (Bieche et al. 1999, 2001a).

The \( N_{\text{target}} \) values of the samples were subsequently normalized such that the median of the ER\( \alpha \)-negative breast tumor values was 1.

**Primers and controls**

Primers for TBP, RPLP0 and the 560 target genes (list in Supplemental data) were chosen with the assistance of the Oligo 5.0 computer program (National Biosciences, Plymouth, MN, USA).

We conducted searches in dbEST, htgs and nr databases to confirm the total gene specificity of the nucleotide sequences chosen as primers, and the absence of single nucleotide polymorphisms. In particular, the primer pairs were selected to be unique relative to the sequences of closely related family member genes or of the corresponding retropseudogenes. To avoid amplification of contaminating genomic DNA, one of the two primers was placed at the junction between two exons, if possible. In general, amplicons were between 70 and 120 nucleotides long. Gel electrophoresis was used to verify the specificity of PCR amplicons.

For each primer pair, we performed no-template control (NTC) and no-reverse-transcriptase control (RT negative) assays, which produced negligible signals (usually >40 in \( C_{T} \) value), suggesting that primer–dimer formation and genomic DNA contamination effects were negligible.

**RNA extraction**

Total RNA was extracted from frozen tumor samples by using the acid–phenol guanidinium method. The quality of the RNA samples was determined by electrophoresis through agarose gels and staining with ethidium bromide, the 18S and 28S RNA bands being visualized under u.v. light.

**cDNA Synthesis**

Total RNA was reverse transcribed in a final volume of 20 µl containing 1 × RT buffer (5 mM each dNTP, 3 mM MgCl2, 75 mM KCl, 50 mM Tris–HCl pH 8.3), 20 units RNasin RNase inhibitor (Promega), 10 mM DTT, 100 units Superscript II RNase H-reverse transcriptase (Invitrogen), 3 µM random hexamers (Pharmacia) and 1 µg total RNA. The samples were incubated at 25 °C for 10 min and 42 °C for 30 min, and reverse transcriptase was inactivated by heating at 99 °C for 5 min and cooling at 4 °C for 5 min.

**PCR amplification**

All PCR were performed using an ABI Prism 7700 Sequence Detection System (Perkin–Elmer Applied Biosystems) and either the TaqMan® PCR Core REAGENTS Kit or the SYBR® Green PCR Core Reagents kit (Perkin–Elmer Applied Biosystems). A 5 µl diluted sample of cDNA (produced from 2 ng total RNA) was added to 20 µl of the PCR master-mix.

The thermal cycling conditions comprised an initial denaturation step at 95 °C for 10 min, and 50 cycles at 95 °C for 15 s and 65 °C for 1 min.

**Statistical analysis**

As the mRNA levels did not fit a Gaussian distribution, (a) the mRNA levels in each subgroup of samples were characterized by their median values and ranges, rather than their mean values and coefficients of variation, and (b) relationships between the molecular markers and clinical and biological parameters were tested.
using the non-parametric Mann–Whitney U-test (Mann & Whitney 1947). Differences between two populations were judged significant at confidence levels greater than 95% ($P < 0.05$).

To visualize the capacity of a given molecular marker to discriminate between two populations (in the absence of an arbitrary cutoff value), we summarized the data in a receiver operating characteristic (ROC) curve (Hanley & McNeil 1982). This curve plots sensitivity (true positives) on the $Y$ axis against 1-specificity (false positives) on the $X$ axis, considering each value as a possible cutoff. The area under curve (AUC) was calculated as a single measure for the discriminatory capacity of each molecular marker. When a molecular marker had no discriminatory value, the ROC curve lies close to the diagonal and the AUC is close to 0.5. In contrast, when a molecular marker has strong discriminatory value, the ROC curve moves to the upper left-hand corner and the AUC is close to 1.0.

### Results

We first determined the mRNA expression level of the 560 selected genes in an ER$\alpha$-positive and an ER$\alpha$-negative breast tumor pools (screening set). These pools were each prepared by mixing identical amounts of tumor RNA from six patients. The mean $TBP$ gene $C_{t}$ (threshold cycle) values for the six individual tumor samples were 25.63 ± 0.28 (ER$\alpha$-positive pool) and 25.82 ± 0.34 (ER$\alpha$-negative pool).

Genes, whose expression in the ER$\alpha$-positive breast tumor pool was at least three times higher than in the ER$\alpha$-negative breast tumor pool were then examined for their mRNA expression in an independent well-characterized series of 24 individual ER$\alpha$-positive breast tumors and 12 ER$\alpha$-negative breast tumors (validation set).

This robust selection criterion ensures the identification of genes of marked interest.

### Expression of the 560 genes in the ER$\alpha$-positive and ER$\alpha$-negative breast tumor pools (screening set)

mRNA levels of 45 (8.0%) of the 560 genes were detectable but not reliably quantifiable by means of real-time quantitative RT-PCR ($C_{t} > 35$), in both the ER$\alpha$-positive and ER$\alpha$-negative breast tumor pools.

Fifty-six (10.8%) of the remaining 517 genes were upregulated (>3-fold) in the ER$\alpha$-positive pool compared with the ER$\alpha$-negative pool.

In contrast, 25 (4.8%) of the 517 genes were downregulated (>3-fold) in the ER$\alpha$-positive pool compared with the ER$\alpha$-negative pool. It is probable that these 25 latter genes are not estrogen-regulated, but correspond rather to genes that are mainly upregulated in undifferentiated tumors (i.e., ER$\alpha$-negative breast tumors), independently of ER$\alpha$ status.

mRNA expression of $ESR1/ER\alpha$, $ESR2/ER\beta$ and 56 candidate genes in 24 individual ER$\alpha$-positive breast tumors and 12 ER$\alpha$-negative breast tumors (validation set)

The expression level of the 56 upregulated genes identified by pooled sample analysis was then determined individually in an independent series of 24 ER$\alpha$-positive breast tumors and 12 ER$\alpha$-negative breast tumors. Fifty-one (91.1%) of the 56 upregulated genes identified by pooled sample analysis were significantly upregulated in the 24 individual ER$\alpha$-positive breast tumors relative to the 12 ER$\alpha$-negative breast tumors ($P < 0.05$; Table 1).

The 51 upregulated genes mainly encoded growth factors and secreted proteins, ($STC2$, $TFF1/IP52$, $SEMA3B$, $IGFBP4$, $BDNF$, $CLU$, $IGFBP5$, $FGF2$, $EGF$ and $CGA$) growth factor receptors ($IL6ST$, $ERBB4$, $PTPRT$, $RET$ and $FGFR2$), transcription factor ($FOXA1$, $PGR$, $BLU$, $GATA3$, $XBPI$, $MYB$, $AR$ and $PAX3$), metabolic enzymes ($CYP2B6$, $CA12$, $ACADS$, $NAT1$, $LRBA$, $SLC7A2$ and $SULT2B1$), and proteins involved in cell proliferation ($p27/CDKN1B$ and $CCND1$) and apoptosis ($BCL2$, $TNFRSF10C/TRAILR3$, $PUMA$, $NOXA$, $DNTP73$, $TATP73$).

The capacity of each of these 51 genes to discriminate between ER$\alpha$-positive and ER$\alpha$-negative breast tumors was then tested by ROC curve analysis. The overall diagnostic values of the 51 molecular markers were assessed in terms of their AUC values (Table 1). Three genes perfectly discriminated between the ER$\alpha$-positive and ER$\alpha$-negative breast tumors (AUC-ROC, 1.000), namely $CYP2B6$, $CA12$ and $IL6ST$. Fig. 1 shows the mRNA levels of these three genes in each of the 24 ER$\alpha$-positive breast tumors and the 12 ER$\alpha$-negative breast tumors.

In the same set of 36 tumors, we also examined the expression of the $ESR2/ER\beta$ gene and found that it was similar in the ER$\alpha$-positive and ER$\alpha$-negative breast tumors (AUC-ROC, 0.502).

The mRNA levels indicated in Table 1 (calculated as described in Materials and methods) show the abundance of the target relative to the endogenous control ($TBP$), used to normalize the starting amount and quality of total RNA. Similar results were obtained with a second endogenous control, $RPLP0$ (also known as 36B4).

Table 1 List of the significantly upregulated genes in the 24 ERα-positive breast tumors relative to the 12 ERα-negative breast tumors.
mRNA expression of the 51 upregulated genes in ER\(\alpha\)-positive breast tumors, according to relapse

Twelve (50%) of the 24 patients with ER\(\alpha\)-positive breast tumors relapsed. Comparison of the median mRNA levels of the 51 genes between patients, who relapsed \((n=12)\) and those who did not relapse \((n=12)\) identified only NAT1 as having significantly different expression \((P=0.024)\).

mRNA expression of the 51 genes in five breast tumor cell lines

The expression level of the 51 genes upregulated in the ER\(\alpha\)-positive breast tumors was then determined in five well-characterized breast tumor cell lines, including two ER\(\alpha\)-positive cell lines (MCF7 and T-47D) and three ER\(\alpha\)-negative cell lines (MDA-MB-231, MDA-MB-435 and SK-BR-3) (Table 2). Fourteen genes \((TFF1/PS2, PGR, FOXA1, GATA3, TATP73, TFF3, KRT18, CA12, ERBB4, TNFRSF10C/TRAIR3, SULT2B1, AR, STC2 and CGA)\) were upregulated \((>3\text{-}fold\) the median value for the ER\(\alpha\)-negative breast tumors) in both ER\(\alpha\)-positive cell lines (MCF7 and T-47D). Seven genes \((SLC7A2, SEMA3B, RET, CLU, DNTPT73, CCND1 and NAT1)\) were upregulated only in the ER\(\alpha\)-positive cell line MCF7, and four other genes \((CYP2B6, RERG, BLU and EGF)\) were upregulated only in the ER\(\alpha\)-positive cell line T-47D. Surprisingly, 9 of these 25 putative ER\(\alpha\)-responsive genes \((FOXA1, TFF3, KRT18, CA12, CGA, SEMA3B, CLU, CYP2B6\)) were upregulated in the ER\(\alpha\)-negative cell line SK-BR-3. Likewise, 26 genes, whose expression was tightly linked to ER\(\alpha\)-positivity of the breast tumor biopsies (Table 1) were not upregulated in any of the cell lines \((SLC39A6, p27/CDKN1B, LRBA, EMS-1, PTPRT, RABEP1, LOC255743, I6GST, TIM14, HPN, BCL2, FGFR2, MYB, IGFBP4, IGFBP5, GJA1, VEGFR1, and RARRES3)\) or were upregulated in the ER\(\alpha\)-negative cell lines \((BDNF\) and \(NOXA\) in MDA-231, PAX23, and \(FGF2\) in MDA-435, PUMA and XBP1 in SK-BR-3, and \(DNAJC12\) and \(ACADSB\) in both MDA-435 and SK-BR-3; Table 2).

mRNA expression of the 51 genes in MCF7 cells treated with E2 (17\(\beta\)-estradiol)

Only 8 of the 51 genes \((PGR, TFF1/PS2, MYB, IGFBP4, RET, NOXA, SEMA3B and CA12)\) were upregulated \((>3\text{-}fold)\) in E2-treated MCF7 cells relative to untreated MCF7 cells (Table 3). Surprisingly, 9 genes were downregulated \((>3\text{-}fold)\) by E2 treatment, namely \(FOXA1, GATA3, SLC7A2, PUMA, CLU, ERBB4, LOC255743, PAX3\) and \(CGA\). It is also
tumors and in 12 ERα characterized series of 24 individual ERα identified were then investigated in an independent well-tumored breast tumor pool (screening set). Thus the 56 genes of interest were present in both ERα-positive breast tumors and an ERα-negative breast tumor pool, by E2 treatment. This finding is noteworthy that the ERα mRNA level was 2.3-fold lower in MCF7 cells treated with E2 than in untreated MCF7 cells, suggesting that E2 might act, via a negative feedback loop, on ER transcription. Finally, the ERβ mRNA level in MCF7 cells was not modified by E2 treatment.

**Discussion**

We first used real-time quantitative RT-PCR to compare the mRNA expression of 560 selected genes in an ERα-positive breast tumor pool and an ERα-negative breast tumor pool (screening set). Thus the 56 genes of interest identified were then investigated in an independent well-characterized series of 24 individual ERα-positive breast tumors and in 12 ERα-negative breast tumors (validation set). Comparison of the pool values with the mean values of the individual samples showed that RNA pooling was an appropriate initial screening approach, significantly limiting the required number of PCR experiments.

Fifty-one (91.1%) of the 56 upregulated genes identified by the pooled sample analysis were significantly upregulated in the individual ERα-positive breast tumors relative to the ERα-negative breast tumors (Table 1). Using the same approach, we have previously shown the involvement of several altered molecular pathways in the genesis of prostate and liver cancer (Latil et al. 2003, Paradis et al. 2003).

Real-time quantitative RT-PCR is a promising complementary methodology to cDNA microarrays for molecular tumor profiling. In particular, real-time RT-PCR is far more precise, reproducible and quantitative than cDNA microarrays. Real-time RT-PCR is also more useful for analyzing weakly expressed genes, such as CGA, BDNF, DNTP73, TATP73 and NOXA in the present study. Finally, real-time RT-PCR requires smaller amounts of total RNA (about 2 ng per target gene), and is therefore suitable for analyzing small or microdissected tumor samples.

We studied a number of genes involved in various cellular and molecular mechanisms that are associated with tumorigenesis and are known to be altered (mainly at the transcriptional level) in various cancers. These genes encode proteins involved in cell cycle control, cell–cell interactions, signal transduction pathways, apoptosis and angiogenesis, etc. (about 10–20 genes were selected per pathway; see list in Supplemental Data which can be viewed online at http://erc.endocrinology-journals.org/supplemental/). After scrutinizing the literature, we also included the well-known ERα-induced genes in breast cancer (PGR, TFF1/PS2, BCL2, CCND1) and a large number of genes that were found to co-cluster with ERα in microarray studies of breast tumor biopsies (Perou et al. 2000, Gruvberger et al. 2001, Sorlie et al. 2001, West et al. 2001, Bertucci et al. 2002, van’t Veer et al. 2002). In consequence, it was not surprising in this present study to identify a large number of genes (51 of the 560 genes tested) significantly upregulated in ERα-positive breast tumors as compared with ERα-negative breast tumors.

This analysis was by no means exhaustive, and many possibly relevant genes were certainly missed, but it nevertheless demonstrates the ability of real-time RT-PCR to identify several potentially useful marker genes.

The first important result obtained in this study is that, in total agreement with Gruvberger et al. (2001), only a small proportion of the 51 genes that co-clustered with ERα status in our breast tumor series were confirmed in vitro to be ERα-regulated (i.e., upregulated in ERα-positive cell lines compared...

with ERα-negative cell lines) and/or E2-regulated (i.e., regulated by E2 in MCF7 cells). There are several possible explanations for these findings. (a) The existence of other ER-signaling pathways, independent of estrogen has been postulated and (Zwijsen et al. 1998, Ding et al. 2003). For example, Sabbah et al. (1999) described a mechanism by which ERα regulates CCND1 gene transcription through a cyclic AMP response element (CRE); (b) Expression of genes in ERα-positive breast tumors can also reflect the presence of different types of epithelial cells in the mammary gland, independently of the presence of estrogen and ERα. In this regard, ERα-positive breast tumors have been suggested to exhibit the phenotype of luminal epithelial cells, whereas ERα-negative tumors resemble myoepithelial (basal) cells (Perou et al. 2000); (c) Downregulation of genes in ERα-negative tumors may also simply reflect dedifferentiation of epithelial cells during malignant progression of ERα-negative breast tumors evolving from ERα-positive precursors; (d) Finally, cultured cell lines (in vitro models) have lost many features that characterize tumor specimens *in vivo* (Welsch et al. 2001, Dangles et al. 2002). The mechanism that leads to *in vivo* gene overexpression in ERα-positive breast tumors involves several factors, including ERα and several known or unknown transcriptional coactivators, not all of, which present in classical *in vitro* models. We were particularly surprised to identify genes that were tightly linked to ERα-positive status in breast tumor biopsies but were downregulated in MCF7 cells after E2 treatment (Table 1). It is also noteworthy that we cannot rule out the possibility that we identified some genes by chance, which can happen when large numbers of variables (gene expressions) are analyzed, in particular the genes showing a weak link to the ERα status.

Our results provide further evidence that gene expression databases based on breast tumor cell lines, used to identify new ERα status markers or new candidate markers of the response to endocrine therapy, must be carefully interpreted (Soulez & Parker 2001, Ngwenya & Safe 2003, Frasor et al. 2003, Vendrell et al. 2004).

A large proportion of the 51 genes identified in this study have previously been reported to be related to ERα status. PGR, TFF1/PS2, BCL2, ERBB4 and CCND1 are well-known ERα-induced genes in breast cancer. Several new genes, such as GATA3, TFF3, MYB, IGFBP4, IGFBP5, STC2, KRT18, HPN/HEPSIN, FOXA1, XB1, SLC39A6/LIV-1 and CA12 M, were recently identified by microarray studies (Gruvberger et al. 2001, Bertucci et al. 2002, van’t Veer et al. 2002). For our part, we have previously identified CGA, NATI
and CYP2B6 as candidate ERα-responsive genes in human breast cancer (Bieche et al. 2001b, 2004b).

In addition, to known ERα-induced genes, we identified an appreciable number of novel genes, and particularly weakly expressed genes, validating our large-scale real-time RT-PCR approach as a method complementary to cDNA microarrays for molecular tumor profiling. These new genes mainly encode secreted proteins and growth factors (BDNF, FGF2, EGF, SEMA3B and CLU), growth factor receptors (IL6ST, PTPRT, RET, VEGFR1 and FGFR2) and metabolic enzymes (CYP2B6, CA12, ACADSB, NAT1, LRBA, SLC7A2 and SULT2B1). Interestingly, in addition to BCL2, we identified a large number of genes encoding proteins involved in apoptosis (TNFRSF10C/TRAILR3, PUMA, NOXA, DNTP73 and TATP73).

DNTP73 and TATP73, produced by alternative splicing of the same gene (TP73), are expressed under the control of two independent promoters and have opposite activities. TAp73 is the transcriptionally active full-length protein, while ΔNp73 is the aminoterminally truncated dominant-negative protein (Melino et al. 2002). Unlike TP53, the genes DNTP73 and TATP73 are mainly regulated at the transcriptional level. TAp73 induces cell-cycle arrest and apoptosis, whereas ΔNp73 inhibits both TAp73-induced and p53-induced apoptosis. Furthermore, ΔNp73 is induced by TAp73 and p53, in a dominant-negative feedback loop that regulates p53 and p73 functions (Melino et al. 2002). NOXA and PUMA are recently identified BH3-only Bcl-2 family proteins, and are key mediators of p53-mediated apoptosis (Fridman & Lowe 2003). PUMA was shown to be downregulated by estradiol and to be associated with OH-Tam resistance in MCF-7-derived cell lines (Vendrell et al. 2005). Finally, TRAILR3 encode a TNF-related apoptosis-inducing-ligand receptor that acts as a decoy receptor for TRAIL, a member of the tumor necrosis factor family (Ashkenazi 2002). In several cell types, decoy receptors inhibit TRAIL-induced apoptosis by binding TRAIL and thereby preventing its binding to pro-apoptotic TRAIL receptors. Surprisingly, we observed upregulation of both pro-apoptotic genes (PUMA, NOXA and TATP73) and anti-apoptotic genes (BCL2, DNTP73 and TRAILR3) in the ERα-positive tumors. Further, studies are needed to determine the respective roles of these apoptotic genes in ERα-positive tumorigenesis.

Identification of genes that co-cluster with ERα status is a first step towards identifying reliable markers with which to predict ERα status or the response to endocrine therapy. In addition, to CYP2B6 and CA12 that are already known to be ERα-related in breast cancer (Gruvberger et al. 2001, Bieche et al. 2004b), we identified a third gene (IL6ST) that perfectly predicted ERα status in our breast tumor series (AUC-ROC, 1.000). IL6ST encodes gp130, the subunit shared by the different receptors of IL-6 family cytokines, including interleukin-6, interleukin-11, leukemia inhibitory factor, oncostatin M, ciliary neurotrophic factor, and cardiotrophin-1 (Kishimoto et al. 1994). Interestingly, Grant et al. (2002) have reported a functional interaction between gp130 and the EGF receptor family in breast cancer cells. However, while these three genes are potentially valuable predictive markers of ERα status, they would be less useful for predicting the response to endocrine therapy, being too strongly linked to ERα. About one-half of all patients with ERα-positive breast tumors fail to respond favorably to antiestrogen treatment, and thus there is a need for new molecular markers with which to identify them. This study identifies new candidate markers of endocrine responsiveness because they are upregulated in only a subgroup of ERα-positive tumors (for example, the genes with AUC-ROC <0.900 in Table 1). Interestingly, some of these genes (JGFBP5, FGF2, CGA, etc.) encode secreted proteins that could serve as serum-based predictive biomarkers. We tested the 51 genes as candidate prognostic molecular markers in our small series of 24 postmenopausal ERα-positive breast cancer patients, who were treated with primary surgery, followed by adjuvant tamoxifen alone, and 12 of them relapsed. The only gene showing significantly different expression ($P = 0.024$) between patients, who relapsed ($n = 12$) and those, who did not relapse ($n = 12$) was NAT1. It is noteworthy that, in a previous study of 125 ERα-positive postmenopausal breast cancer patients, we identified NAT1 and CGA (also identified in the present study) as independent predictors of the response to tamoxifen (Bieche et al. 2001b, 2004b).

Some results of this study – identification of new ERα-induced genes, the three genes (CYP2B6, CA12, IL6ST) that highly predicted ERα status and new candidate markers of endocrine responsiveness must now be confirmed in larger series of breast tumors.

In conclusion, by using a large-scale real-time quantitative RT-PCR approach, we identified 51 genes that co-cluster with ERα status. Many of these genes were identified for the first time as being linked to ERα status and several are involved in apoptosis (TNFRSF10C/TRAILR3, PUMA, NOXA, DNTP73 and TATP73). These 51 genes should help to delineate the estrogen receptor pathway and function, and some of the genes may prove useful for developing diagnostic tests or new markers of responsiveness to the different
available strategies of endocrine therapy (aromatase inhibitor, tamoxifen or pure antiestrogen).
