Abstract

To clarify the role of metabolic factors in endometrial carcinogenesis, we conducted a case–control study nested within the European Prospective Investigation into Cancer and Nutrition (EPIC), and examined the relation between prediagnostic plasma lipids, lipoproteins, and glucose, the metabolic syndrome (MetS; a cluster of metabolic factors) and endometrial cancer risk. Among pre- and postmenopausal women, 284 women developed endometrial cancer during follow-up. Using risk set sampling, 546 matched control subjects were selected. From conditional logistic regression models, high-density lipoprotein cholesterol (HDL-C) levels were inversely associated with risk body mass index (BMI)-adjusted relative risk (RR) for top versus bottom quartile 0.61 (95% confidence intervals (CI) 0.38–0.97), $P_{\text{trend}}=0.02$). Glucose levels were positively associated with risk (BMI-adjusted RR top versus bottom quartile 1.69 (95% CI 0.99–2.90), $P_{\text{trend}}=0.03$), which appeared stronger among postmenopausal women (BMI-adjusted RR top versus bottom tertile 2.61 (95% CI 1.46–4.66), $P_{\text{trend}}=0.0006$, $P_{\text{heterogeneity}}=0.13$) and never-users of exogenous hormones ($P_{\text{heterogeneity}}=0.005$ for oral contraceptive (OC) use and 0.05 for hormone replacement therapy-use). The associations of HDL-C and glucose with risk were no longer statistically significant after further adjustment for obesity-related hormones. Plasma total cholesterol, Low-density lipoprotein cholesterol (LDL-C), and triglycerides were not significantly related to overall risk. The presence of MetS was associated with risk (RR 2.12 (95% CI 1.51–2.97)), which increased with the number of MetS factors ($P_{\text{trend}}=0.02$). An increasing number of MetS factors other than waist circumference, however, was marginally significantly associated with risk only in women with waist circumference above the median ($P_{\text{interaction}}=0.01$). None of the associations differed significantly by fasting status. These findings suggest that metabolic abnormalities and obesity may act synergistically to increase endometrial cancer risk.

Endocrine-Related Cancer (2007) **14** 755–767

Introduction

Endometrial cancer development is strongly linked to lifestyle factors (Kaaks *et al.* 2002). Excess weight is a major risk factor (Kaaks *et al.* 2002) that is estimated to cause up to half of all endometrial cancer cases in developed countries (Calle & Kaaks 2004). The biologic mechanism through which obesity increases risk is primarily by increasing levels of bioavailable estrogens and reducing levels of progesterone, leading to increased mitotic activity of endometrial cells (Key & Pike 1988, Kaaks *et al.* 2002).

There is increasing evidence that insulin resistance (Cust *et al.* 2007b), hyperinsulinemia (Lukanova *et al.* 2004, Cust *et al.* 2007a), and diabetes (Weiderpass *et al.* 2000) are implicated in the etiology of endometrial cancer, but little is known about the possible role of other related metabolic factors such as hypertension, elevated glucose levels, or unfavorable lipid profiles. Some of these factors may interact with obesity, as several studies have found an increased risk of endometrial cancer associated with hypertension (Weiderpass *et al.* 2000, Furberg & Thune 2003), diabetes (Shoff & Newcomb 1998, Salazar-Martinez *et al.* 2000, Anderson *et al.* 2001), and glucose levels (Furberg & Thune 2003), among overweight or obese women only. Few studies of sufficient size (Hiatt & Fireman 1986, Swanson *et al.*

1994) have assessed the relation between lipid and lipoprotein levels and endometrial cancer risk. Prospective studies are needed because the presence or diagnosis of a tumor can lead to alterations in lipid metabolism (Law & Thompson 1991).

Several of these metabolic factors are components of the metabolic syndrome (MetS), which is a cluster of endocrine–metabolic disturbances characterized by insulin resistance, impaired glucose regulation, hypertension, and a lipid profile consisting of raised triglycerides and low high-density lipoprotein cholesterol (HDL-C; Alberti *et al.* 2006). It is unknown whether a diagnosis of the MetS or its component factors might be a better predictor of endometrial cancer risk over and above the risk associated with obesity. Furthermore, there have not been any prospective studies, so far, examining the association between the MetS and endometrial cancer risk.

Thus, there were two main objectives of this prospective study: 1) to assess the risk of endometrial cancer in relation to baseline plasma levels of total cholesterol, HDL-C, low-density lipoprotein cholesterol (LDL-C), triglycerides, and glucose, and how these associations are confounded by obesity and other obesity-related biologic markers, including adiponectin, C-peptide, insulin-like growth factor binding proteins (IGFBPs)-1 and -2, and endogenous sex steroid

hormones and 2) to examine the association between MetS and endometrial cancer risk. To assess these associations, we designed a case–control study among 284 incident cases of endometrial cancer in pre-, peri-, and postmenopausal women and 546 matched controls, nested within the European Prospective Investigation into Cancer and Nutrition (EPIC) cohort study.

Materials and methods

Study population, baseline data collection, and follow-up

The EPIC study design, population, baseline data collection, and follow-up procedures for cancer incidence and vital status have been described previously in detail (Riboli & Kaaks 1997, Riboli *et al.* 2002). Briefly, ~366 500 women and 153 500 men in ten western European countries joined the study between 1992 and 1998, and of these, about 386 000 also provided a blood sample. The present study includes subjects from eight of the ten participating countries: Denmark, France, Germany, Greece, Italy, The Netherlands, Spain, and the UK. Norway was not included in the present study because blood samples were collected only recently, and very few cases of endometrial cancer had been diagnosed when the present study was initiated. Sweden was not included because a separate study within their cohort had already been planned.

Previous papers describe the baseline assessment of usual diet and lifestyle factors (Riboli *et al.* 2002), physical activity (Haftenberger *et al.* 2002a), and anthropometric measures (Haftenberger *et al.* 2002b). At the time of blood donation, women were classified as premenopausal if they reported having had regular (>9) menstrual cycles over the previous 12 months; postmenopausal if they reported not having had any menses over the past 12 months or if they had a bilateral ovariectomy; and perimenopausal/unknown if they reported one to nine cycles over the past 12 months. Women with incomplete, missing, or equivocal questionnaire data for menopausal status were classified as premenopausal if they were less than 42 years of age, perimenopausal/unknown if they were between 42 and 55 years of age, and postmenopausal if they were older than 55 years.

In Denmark, Italy, The Netherlands, the UK, and Spain, incident cancer cases were identified through record linkage with regional cancer registries. In Germany, France, and Greece, follow-up was based on a combination of methods, including health insurance records, cancer and pathology registries, and active follow-up through study subjects and their next of kin.

Data on vital status in most EPIC study centers were collected from mortality registries at the regional or national level, in combination with data collected by active follow-up (Greece). Vital status was known for 98.4% of all EPIC participants as of April 2004. For each EPIC study center, closure dates of the study period were defined as the date of the last complete follow-up for both cancer incidence and vital status (dates varied between June 1999 and December 2003 between centers). All participants gave written consent for future analyses of their blood samples, and the study was approved by the local ethics committees in the participating countries and the Internal Review Board of the IARC.

Selection of case and control subjects

Women were excluded from being a case or control for this study if, at the time of blood donation, they had a previous cancer diagnosis (except non-melanoma skin cancer), or had a hysterectomy. Current users of oral contraceptives (OCs) or hormone replacement therapy (HRT) were also excluded, since they are known to modify hormone and lipid levels and lipoprotein composition (Bradley *et al.* 1978, Wallace *et al.* 1979), and may also have effects on glucose levels and blood pressure (Elgee 1970, Medina *et al.* 2004) depending on the dose and potency of the estrogens and progestins used. We further excluded endometrial tumors of known non-epithelial or non-malignant morphology (World Health Organization 2003). A total of 135 953 women from the eight participating countries met these eligibility criteria, of whom 300 women were diagnosed with endometrial cancer during the follow-up period. After further exclusion of 16 cases with insufficient blood sample volume, there were 284 cases included in this study, comprising 67 cases in Denmark, 61 in Italy, 41 in Spain, 36 in The Netherlands, 34 in the UK, 19 in Germany, 17 in France, and 9 in Greece. The cancer diagnosis was confirmed by microscopy (92%), clinical examination (7%), or self-report, tomography scan, surgery, or autopsy (1%). Tumor morphology was specified for 142 cases (50%), of which 133 cases (94%) were classified as type I (mainly endometrioid and some mucinous adenocarcinomas) and 9 cases (6%) as type II (serous papillary, clear cell, or squamous adenocarcinomas; Sherman 2000, World Health Organization 2003).

Control subjects were chosen at random among risk sets consisting of all eligible cohort members alive and free of cancer (except non-melanoma skin cancer) at the time of diagnosis of the index case. An incidence density sampling protocol for control selection was used, such that controls were matched to cases on time

at risk, and controls could include subjects who later became a case, while each control could also be sampled more than once. Matching criteria included: study center, menopausal status (premenopausal, perimenopausal/unknown, and postmenopausal), age at blood collection (± 6 months), time of day of blood collection (± 1 h), time between blood draw and last consumption of foods or drinks (< 3 h (41.8%), 3–6 h (20.8%), > 6 h (32.1%), unknown (5.3%)), and for premenopausal women, phase of menstrual cycle (Kaaks et al. 2005). Two matched controls were identified for 262 cases, and only one matched control could be identified for 22 cases (total of 546 controls).

Blood collection and storage

A 30 ml blood sample was collected according to a standardized protocol. Filled syringes were kept at 5–10 °C, protected from light, and transferred to a local laboratory for further processing and aliquoting, with the exception of subjects recruited through the Oxford center, where blood samples were transported to a laboratory in Norfolk by mail at ambient temperature. Plasma lipids, lipoproteins, and endogenous hormones have been shown to be fairly stable after storage or transport at ambient temperatures for up to 72 h (Hankinson et al. 1989, Boyanton & Blick 2002), however, in whole blood, glucose concentrations can degrade rapidly at room temperature within 24 h (Boyanton & Blick 2002). Therefore, we excluded glucose values from all 35 women recruited at the Oxford center. Blood fractions (serum, plasma, red cells, and buffy coat for DNA extraction) were aliquoted into straws, heat-sealed, and stored in liquid nitrogen tanks at -196 °C, except in Denmark where samples were stored in 1 ml tubes in nitrogen vapor at -150 °C.

Hormone assays

Lipid, lipoprotein, and glucose assays were performed at Hôpital Edouard Herriot, Lyon, France, and the other hormone assays were performed at the IARC by laboratory staff blinded to the case–control status of the study subjects. The plasma samples of each matched case–control set were analyzed with sets from the same center, within the same batch on the same day. Cholesterol, HDL-C, and glucose were measured using enzymatic (hexokinase) colorimetric tests, and triglycerides were measured using an enzymatic (GPO-PAP) colorimetric test (Roche Diagnostics). LDL-C was estimated using the Friedewald equation (Friedewald et al. 1972). The intra- and inter-batch coefficients of variation (CV) were 0.8 and 2.1% for total cholesterol, 1.2 and 2.4% for triglycerides, 1.2 and 1.7% for HDL-C,

and 0.8 and 2.1% for glucose. Plasma adiponectin and serum C-peptide, IGF1Ps-1 and -2, and endogenous sex steroid hormones (testosterone, estrone, sex hormone-binding globulin (SHBG), free testosterone and, in postmenopausal women, total and free estradiol) have previously been analyzed and reported (Cust et al. 2007a,b).

Presence of the MetS

The presence of the MetS at baseline was determined for all women (both fasting and non-fasting combined) using two definitions: 1) the National Cholesterol Education Program (NCEP) – Adult Treatment Panel III (Grundey et al. 2005) and 2) the International Diabetes Federation (IDF) definition (Alberti et al. 2006). For the NCEP MetS definition, the presence of three or more of the following five components was required: waist circumference ≥ 88 cm, triglycerides ≥ 1.7 mmol/l, HDL-C < 1.29 mmol/l, systolic blood pressure ≥ 130 mmHg or diastolic blood pressure ≥ 85 mmHg, and glucose ≥ 5.6 mmol/l. The diagnosis of MetS according to the IDF definition required a waist circumference ≥ 80 cm, plus the presence of two or more other components: elevated triglycerides, low HDL-C, raised blood pressure, or impaired glucose metabolism, using the same cut-points as the NCEP.

A total of 280 cases and 535 matched controls were included in the MetS analyses. A combination of measured and self-reported data was used for the blood pressure and glucose criteria. There were 518 (64%) women with both measured blood pressure and self-reported hypertension data; 182 (22%) had measured blood pressure only and 115 (14%) women had self-reported data only. Of the 700 women (87% of controls and 84% of cases) with measured systolic and diastolic blood pressure, the mean of two measurements was available for 435 (62%) subjects. For the glucose criteria, 776 (95%) women had both plasma glucose values and self-reported diabetes data, 12 (1%) had measured plasma glucose only and 27 women (3%; mostly Oxford subcohort) had self-reported data only. Individuals receiving pharmacologic treatment for hypertension, hypertriglyceridemia or low HDL-C, or subjects diagnosed with type 2 diabetes, are considered as meeting the respective criteria. However, apart from self-reported hypertension and diabetes, data on pharmacologic treatments were not available for this analysis.

Statistical analyses

Circulating lipid, lipoprotein, glucose, and hormone levels were log transformed to normalize their distributions. Pearson's partial correlation coefficients,

adjusted for age at blood collection, laboratory batch, and case–control status, were estimated to assess correlations.

Conditional logistic regression models were used to estimate relative risks (RRs) and 95% confidence intervals (CIs) for the associations between exposure variables and endometrial cancer risk. The prospective design and use of incidence density sampling for selecting controls in this study permitted the direct estimation of the RR rather than the odds ratio (Richardson 2004). Quartile cut-points (or tertile cut-points for subgroup analyses) were based on the distribution of the variable in control subjects in the full study group; these same cut-points were also used for the subgroup analyses. Fasting and non-fasting women had similar geometric mean baseline levels of total cholesterol, HDL-C, LDL-C, and glucose, but triglyceride levels differed significantly by fasting status, after accounting for case–control status, age, laboratory batch, and body mass index (BMI) in an analysis of covariance (data not shown). Thus, for triglycerides, different cut-points were used according to fasting status. Likelihood ratio tests using medians for each quantile category were used to assess linear trends in RRs.

Multivariate models for the analyses of lipids, lipoproteins, and glucose were adjusted for BMI in addition to matching variables. Results were similar when models were adjusted for waist circumference instead of BMI. The average plasma sample storage time was identical for cases and controls (10.4 years), and additional adjustment for storage time did not affect the results. We also examined other potential confounders including age at menarche, age at menopause, parity, age at birth of last child, previous OC use, previous HRT use, smoking status, physical activity level, alcohol intake, average daily glycemic load and glycemic index, and education level. However, the inclusion of these other potential confounders in the regression models did not appreciably change the risk estimates and thus were not included in the regression models. In addition, we examined the effect of adjusting for circulating levels of endogenous sex steroid hormones and other obesity-related hormones (quartiles, missing). For the MetS multivariate models, we adjusted for waist circumference or mutually adjusted for the individual component MetS factors.

We also examined the possibility of effect modification by menopausal status, fasting status (≤ 6 h, > 6 h since last food or drink), BMI (median cut-point: < 26.2 , ≥ 26.2 kg/m²), physical activity level (metabolic equivalent (MET)-h/week, median cut-point), use of OCs or HRT (previous use, never-use), time to diagnosis (< 2 years, ≥ 2 years), and country. χ^2 tests, calculating

the deviations of logistic β -coefficients observed in each of the subgroups relative to the overall β -coefficient, were used to examine heterogeneity of BMI-adjusted risk estimates associated with a doubling (log2) of lipid, lipoprotein, or glucose levels. For the MetS analyses, interactions were examined by adding appropriate interaction terms to the models. All analyses were performed using SAS Statistical Software (version 9.1, SAS Institute, Cary, NC, USA), and statistical significance was inferred at two-sided $P < 0.05$.

Results

Baseline characteristics according to case–control status are described in Table 1. The mean age of women at baseline was 56.9 years. Compared with control subjects, women who developed endometrial cancer during follow-up were more likely to be obese, nulliparous, report having hypertension, have a later age at menopause or earlier age at menarche, and were less likely to have used OCs in the past.

Pearson's partial correlation coefficients, adjusted for age at blood collection, laboratory batch, and case–control status are shown in Table 2. Plasma HDL-C levels were negatively correlated with triglycerides ($r = -0.54$), glucose ($r = -0.15$), LDL-C ($r = -0.15$), C-peptide ($r = -0.36$), estrogens, free testosterone, measures of adiposity, and (weakly) with glycemic load. Conversely, HDL-C levels were positively correlated with adiponectin ($r = 0.46$), SHBG ($r = 0.34$), and IGFBP-1 and -2. Total and LDL cholesterol were not correlated with most other factors (data not shown). Glucose and triglycerides were positively correlated with C-peptide ($r = 0.26$ and 0.41 respectively) and adiposity, weakly correlated with androgens and estrogens, and negatively correlated with SHBG, IGFBP-1 and -2. The correlations were generally slightly lower after additional adjustment for BMI or waist circumference (data not shown).

In conditional logistic regression analyses adjusted for matching factors only, increasing triglyceride and glucose levels were associated with increased endometrial cancer risk, HDL-C levels were inversely associated with risk, and total cholesterol and LDL-C levels were not associated with risk (Table 3). One of our objectives was to examine how these associations may be confounded by obesity and other obesity-related biologic markers. After adjustment for BMI, the associations remained statistically significant for HDL-C and glucose but not for triglycerides (Table 3). When total cholesterol, HDL-C, LDL-C, triglycerides, and glucose were each mutually adjusted in addition to BMI-adjustment, only the glucose association remained

Table 1 Baseline characteristics for women who developed endometrial cancer during follow-up (cases) and control subjects, in a case–control study nested in the European Prospective Investigation into Cancer and Nutrition (EPIC) cohort

^bCalculated using two-sided paired *t*-tests for continuous variables and χ^2 tests for categorical variables.

^cEstimated as MET-h/week.

^dAmong postmenopausal women.

statistically significant ($P_{\text{trend}}=0.008$; data not shown). None of the associations remained statistically significant after further adjustment for sex steroid hormones and other obesity-related hormones (Table 3).

When stratified by baseline menopausal status (Table 4), plasma glucose levels were associated with significantly increased risk among postmenopausal women, but not among perimenopausal/unknown or premenopausal women ($P_{\text{heterogeneity}}=0.13$). Stratification by the median BMI showed stronger and statistically significant associations between HDL-C, glucose, and endometrial cancer risk among women above the median, and modest non-significant associations among women below the median, although the tests for heterogeneity were not statistically significant ($P_{\text{heterogeneity}}=0.09$ for HDL-C and 0.51 for glucose).

In this cohort, 18% (22% cases, 16% controls) of postmenopausal women had previously used HRT and 39% (32% cases, 42% controls) of all women had previously used OCs. In stratified analyses, plasma glucose levels were associated with an increased risk

among never-users of OCs or HRT, but there was no association among previous users. The BMI-adjusted RR associated with a doubling of glucose levels was 0.29 (95% CI 0.06–1.38) for previous OC users, 3.88 (95% CI 1.54–9.77) for never OC users, $P_{\text{heterogeneity}}=0.005$; and 0.10 (95% CI 0.00–3.63) for previous HRT users, 3.85 (95% CI 1.50–9.88) for never HRT users, $P_{\text{heterogeneity}}=0.05$. The associations did not significantly differ by fasting status, physical activity, time to cancer diagnosis, or country. For triglycerides, the BMI-adjusted RR for the top versus bottom quartile among fasting subjects was 1.58 (95% CI 0.69–3.63), $P_{\text{trend}}=0.17$ and among non-fasting subjects was 1.18 (95% CI 0.70–2.00), $P_{\text{trend}}=0.46$. The RR estimates did not appreciably change when we excluded non-type I cases or cases diagnosed within 2 years after study entry.

The presence of MetS was associated with increased risk of endometrial cancer (Table 5). The association was stronger using the NCEP definition (RR 2.12 (95% CI 1.51–2.97)) than the IDF definition (RR 1.68 (95% CI 1.23–2.31)). The NCEP RR was attenuated by about half after adjustment for waist circumference, suggesting that

obesity explained much of the increased risk, but the association remained statistically significant. The MetS–risk association was not modified by menopausal status, fasting status, previous exogenous hormone use, or physical activity ($P_{\text{interaction}}$ all > 0.10). The RRs associated with the MetS (NCEP definition) among pre, peri/unknown, postmenopausal were 1.89 (95% CI 0.75–4.73), 5.90 (95% CI 1.63–21.35), and 1.92 (95% CI 1.30–2.82) respectively. The NCEP MetS RR was 2.33 (95% CI 1.24–4.38) among fasting women and 1.90 (95% CI 1.25–2.87) among non-fasting women using the same standard cut-points. We additionally examined the MetS RR among non-fasting women only (≤ 6 h; 62.8% of women) using the non-fasting top quartiles of triglycerides (> 1.74 mmol/l) and glucose (> 4.82 mmol/l), and the non-fasting bottom quartile of HDL-C (< 1.13 mmol/l) as cut-points for those variables while keeping the other cut-points the same; the RR was 2.05 (95% CI 1.33–3.16).

We also examined the individual component factors that contribute to the MetS (Table 5). Overall, 19% of subjects had no NCEP MetS factors, and 31, 23, 17, 9, and 1% of subjects had 1–5 factors respectively. Waist

circumference was strongly associated with endometrial cancer risk, even after adjustment for the other MetS factors. The diagnosis of an increasing number of MetS factors was associated with a significantly increased endometrial cancer risk (crude $P_{\text{trend}} < 0.0001$; Table 5). Similar results were found when stratified by fasting status (fasting, $P_{\text{trend}} = 0.01$; non-fasting, $P_{\text{trend}} = 0.0007$; data not shown). An increasing number of the four non-waist circumference factors was associated with a marginally significant increasing risk only among women whose waist circumference was above the median (≥ 83 cm; $P_{\text{trend}} = 0.06$) but not below the median ($P_{\text{trend}} = 0.69$; $P_{\text{interaction}} = 0.01$; Table 5).

The presence of raised blood pressure according to the MetS criteria was not associated with endometrial cancer risk (Table 5). Using quartile cut-points, the RRs for the highest versus lowest quartile for systolic and diastolic blood pressure after adjustment for the other NCEP MetS factors were 1.40 (95% CI 0.81–2.40), $P_{\text{trend}} = 0.28$ and 1.32 (95% CI 0.77–2.25), $P_{\text{trend}} = 0.45$ respectively. Self-reported hypertension was associated with a marginally significant increased risk (adjusted RR 1.47 (95% CI 0.96–2.24)).

Discussion

In this prospective study, HDL-C levels were inversely associated with endometrial cancer risk, and glucose levels were positively associated with risk particularly among women who were postmenopausal or who had never used exogenous hormones. Total cholesterol, LDL-C, and triglyceride levels were not related to overall risk independent of BMI. The MetS was associated with an increased risk; this association was predominantly attributable to abdominal obesity, however, a clustering of the other MetS metabolic abnormalities was additionally associated with risk especially among overweight women.

Major strengths of this study are the relatively large sample size, and the prospective design that minimizes selection bias arising from inappropriate selection of control subjects. The prospective collection of blood samples at baseline, prior to cancer diagnosis, also avoids reverse causation bias that often occurs in studies of circulating lipid exposures (Law & Thompson 1991). Laboratory variability was minimized using a central laboratory for lipid and hormone measurements, with blood samples from cases and their matched control subjects collected under identical conditions and always assayed together in the same batch.

A limitation of our study was the mixture of fasting and non-fasting blood samples in our study. Although

^aAdjusted for matching factors only: study center, baseline menopausal status, age at blood collection, time of day of blood collection, fasting status, and in premenopausal women, phase of menstrual cycle.

^bIn addition to adjustment for matching factors, the models were mutually adjusted for the other factors in this table, as well as BMI, C-peptide, IGFBP-1, -2, adiponectin, SHBG, free testosterone, and estrone.

^cFor triglycerides, different cut-points were used according to fasting status; cut-points for fasting subjects (*n*=266) were ≤0.71, 0.72–0.91, 0.92–1.15, ≥1.16; cut-points for non-fasting subjects (*n*=520) were ≤0.91 0.92–1.25, 1.26–1.66, ≥1.67. A total of 15 cases and 29 matched controls with unknown fasting status were excluded from triglyceride analyses.

^dExcludes all 35 women recruited at the Oxford center.

total cholesterol and HDL-C levels are unaffected by acute fasting status, non-fasting measurements of triglycerides, glucose, and LDL-C may be less reliable because they can be influenced by recent food intake (Ahmed *et al.* 1976, Rifai *et al.* 1990, Wilder *et al.* 1995). Nevertheless, only triglyceride levels differed by fasting status in our study; thus, we used different quartile cut-points for fasting and non-fasting triglyceride levels. We also matched cases and controls according to fasting status and time of day of blood collection in order to minimize this variation. Although the risk estimates were generally slightly lower among non-fasting than fasting women, none of these differences were statistically significant.

Another limitation was the use of a single measurement from one baseline blood sample that does not fully

reflect long-term circulating levels. Other studies have found little intra-individual variation in levels of total cholesterol, HDL-C, LDL-C, and glucose over a 1-year period (Demacker *et al.* 1982, Shumak & Campbell 1993, Muti *et al.* 2002). However, triglycerides may be subject to considerable biologic variation even in fasting samples (Demacker *et al.* 1982, Shumak & Campbell 1993). Another potential source of variation is from long-term storage. Average decreases in lipid and lipoprotein concentrations of about 1–3% per year have been observed when stored at –70 to –80 °C up to 7 years (Kronenberg *et al.* 1994, Shih *et al.* 2000). Glucose concentrations in plasma stored at –20 °C may degrade up to 10% over 1 year (Clark *et al.* 1990), however, less degradation is expected in EPIC samples, which were stored at –196 °C.

^aTertile cut-points (mmol/l) were based on the distribution of the variable among control subjects in the full study group.

^bThe analysis was matched on study center, baseline menopausal status, age at blood collection, time of day of blood collection, fasting status, and in premenopausal women, phase of menstrual cycle. Additional adjustment was made for BMI.

^cExcludes all 35 women recruited at the Oxford center.

We observed an inverse association between HDL-C levels and endometrial cancer risk in our study. In a cross-sectional study of premenopausal women (Furberg *et al.* 2005), low serum HDL-C was associated with increased free estradiol levels but unchanged progesterone levels, thus reflecting increased exposure to unopposed estrogens that is a major etiologic determinant of endometrial cancer (Kaaks *et al.* 2002). Similarly in our study, HDL-C levels were negatively correlated with estrogens, measures of adiposity, and C-peptide and positively correlated with SHBG and adiponectin. Endogenous sex steroid hormones, particularly androgens, regulate HDL-C and other lipid levels through their action on hepatic triglyceride lipase activity and lipolysis (Haffner & Valdez 1995). Although it has been proposed that low HDL-C could be a potential relevant marker for endometrial cancer risk (Furberg *et al.* 2005), the HDL–risk association was not independent of other obesity-related hormones in our study. Consistent with our findings, a previous prospective study with 448 cases (Hiatt & Fireman 1986) also found no overall association between total cholesterol levels and risk. Another prospective study with 130 cases (Furberg & Thune 2003) observed weak age-adjusted inverse associations between serum total cholesterol, HDL-C and risk, and no association with triglycerides.

High glucose levels could increase risk by acting as an energy source for the proliferation of tumor cells (Goldman *et al.* 2006), generating free radicals, or causing oxidative damage to DNA and DNA repair

enzymes (Sun 1990, Dandona *et al.* 1996). Glucose transporter (GLUT) 1, 4, and 8 expression is upregulated in endometrial cancer cells, and may be linked to tumor progression and differentiation (Goldman *et al.* 2006, Shibata *et al.* 2007). Previous, smaller, prospective (Furberg & Thune 2003), and case–control (Levrán *et al.* 1984, Rutanen *et al.* 1993) studies have also observed increased risks associated with high glucose levels. In addition, type 2 diabetes, which is characterized by elevated glucose and insulin levels, is associated with increased endometrial cancer risk (Weiderpass *et al.* 2000, Anderson *et al.* 2001). Uterine GLUT expression and glucose transport are differentially regulated by estrogen and progesterone (Medina *et al.* 2004), and thus may be influenced by endogenous hormones and previous or current use of HRT or OCs. This effect might explain the stronger associations between glucose and endometrial cancer risk among never-users compared with previous users in our study. Future studies should address the potential modifying effect of OC or HRT on glucose pathways, according to the dose and potency of the estrogens and progestins in the formulations.

The presence of the MetS at baseline was associated with a 2.1-fold increased endometrial cancer risk using the NCEP definition and a 1.7-fold increased risk using the IDF definition. The difference in RRs between the definitions is likely to be due to the different obesity cut-points, as obesity is strongly associated with endometrial cancer (Kaaks *et al.* 2002). As data on pharmacologic treatments were not available, it is possible that we have slightly underestimated the

Table 5 Relative risk estimates for endometrial cancer according to the diagnosis of metabolic syndrome and its component factors at baseline, in all women

^aPercent of cases (total=280) and controls (total=535) that were classified as meeting the respective criteria.
^bThe analysis was matched on study center, baseline menopausal status, age at blood collection, time of day of blood collection, fasting status, and in premenopausal women, phase of menstrual cycle.
^cAbdominal obesity, by definition, is a component of the MetS. However, these models were additionally adjusted for waist circumference as a continuous variable to estimate the extent to which the increased risk could be explained by obesity.
^dThe reference category for each factor included women not meeting the respective criteria. Raised blood pressure was defined as systolic blood pressure ≥130 mmHg or diastolic blood pressure ≥85 mmHg or self-reported hypertension. Impaired glucose metabolism was defined as glucose ≥5.6 mmol/l or self-reported diabetes.
^eIndividual component factors were mutually adjusted for the other MetS metabolic factors (categories) and waist circumference (continuous).
^fThe highest two categories were combined due to few numbers in the highest category.
^gAdditionally adjusted for waist circumference as a continuous variable.

prevalence of MetS in our study population, and the RRs may be slightly over- or underestimated. Another prospective study (Furberg & Thune 2003) reported a 1.9-fold increased risk (95% CI 0.84–4.34) associated with a cluster of similar metabolic abnormalities (excluding obesity), but only six cases were included in their analysis. In our study, the MetS–risk association may be largely explained by the presence of abdominal obesity. In postmenopausal women, the conversion of

androgens to estrogens occurs in adipose tissue, thus the level of adiposity directly influences the amount of circulating estrogens (Key & Pike 1988, Kaaks et al. 2002). In premenopausal women, obesity can cause anovulation and decreased progesterone and estrogen levels (Kaaks et al. 2002).
In addition, obesity is a major determinant of insulin resistance (Bergman & Mittelman 1998), and they are both key characteristics of the MetS (Grundy et al.

2005). Insulin resistance (Cust *et al.* 2007b) and hyperinsulinemia (Lukanova *et al.* 2004, Cust *et al.* 2007a) may also be associated with increased endometrial cancer risk independently of obesity. Insulin may act directly on endometrial tissue as a mitogenic and anti-apoptotic growth factor (Nagamani & Stuart 1998). Insulin can also increase IGF-I bioactivity (Kaaks & Lukanova 2001, Kaaks *et al.* 2002), and increase the bioavailability of free estrogens and androgens through downregulation of SHBG and upregulation of ovarian sex steroid production (Kaaks & Lukanova 2001, Kaaks *et al.* 2002).

Overall, there was a statistically significant dose–response trend between the number of MetS metabolic abnormalities and endometrial cancer risk. Although interrelated, these factors may reflect different aspects of an underlying metabolic disturbance, and the presence of more factors may express less misclassification. This relation could be confounded by obesity because the presence of other metabolic abnormalities may be related to higher levels of adiposity; however, the association remained statistically significant after finer adjustment for waist circumference.

Further analysis showed that the dose–response trend between the number of non-waist MetS factors and risk was more evident among women above the median waist circumference. Several other studies have also reported potential modifying effects of obesity on associations between metabolic disturbances and risk. In some studies, hypertension (Weiderpass *et al.* 2000, Furberg & Thune 2003), diabetes (Shoff & Newcomb 1998, Salazar-Martinez *et al.* 2000, Anderson *et al.* 2001), glucose levels (Furberg & Thune 2003), and the consumption of high-glycemic load foods (Larsson *et al.* 2007) have been found to be positively associated with endometrial cancer risk only among overweight or obese women. Low adiponectin levels (a marker of insulin resistance) are also associated with increased risk particularly among obese women (Cust *et al.* 2007b), and low serum HDL-C levels and a high LDL-C/HDL-C ratio have been found to predict increased bioavailable estradiol levels more strongly among overweight than normal-weight women (Furberg *et al.* 2005). Thus, overweight women may experience a heightened physiologic response to the presence of other metabolic factors compared with leaner women.

In conclusion, these findings support the hypothesis that obesity and other metabolic disturbances may act synergistically to facilitate malignant transformation of endometrial cells (Furberg & Thune 2003). Further prospective epidemiologic and experimental studies are needed to clarify the underlying biologic mechanisms for these associations. Strategies to reduce the incidence of

endometrial cancer should target the prevention and treatment of obesity and related metabolic disorders.
