Abstract

One of the mechanisms through which advanced prostate cancer (PCa) usually relapses after androgen deprivation therapy (ADT) is the adaptation to residual androgens in PCa tissue. It has been observed that androgen biosynthesis in PCa tissue plays an important role in this adaptation. In the present study, we investigated how stromal cells affect adrenal androgen dehydroepiandrosterone (DHEA) metabolism in androgen-sensitive PCa LNCaP cells. DHEA alone had little effect on prostate-specific antigen (PSA) promoter activity and the proliferation of LNCaP cells. However, the addition of prostate stromal cells or PCa-derived stromal cells (PCaSC) increased DHEA-induced PSA promoter activity via androgen receptor activation in the LNCaP cells. Moreover, PCaSC stimulated the proliferation of LNCaP cells under physiological concentrations of DHEA. Biosynthesis of testosterone or dihydrotestosterone from DHEA in stromal cells and LNCaP cells was involved in this stimulation of LNCaP cell proliferation. Androgen biosynthesis from DHEA depended upon the activity of various steroidogenic enzymes present in stromal cells. Finally, the dual 5\(\alpha\)-reductase inhibitor dutasteride appears to function not only as a 5\(\alpha\)-reductase inhibitor but also as a 3\(\beta\)-hydroxysteroid dehydrogenase inhibitor in LNCaP cells. Taken together, this coculture assay system provides new insights of coordinate androgen biosynthesis under the microenvironment of PCa cells before and after ADT, and offers a model system for the identification of important steroidogenic enzymes involved in PCa progression and for the development of the corresponding inhibitors of androgen biosynthesis.

Endocrine-Related Cancer (2009) 16 1139–1155

Introduction

Prostate cancer (PCa) is the most common malignancy and the second leading cause of cancer-related death of men in the United States (Jemal \textit{et al.} 2008). Since advanced PCa is initially dependent upon androgens, androgen deprivation therapy (ADT) is the first choice for advanced PCa. Unfortunately, after an initial response to ADT, PCa eventually loses responsiveness to the androgen blockade and progresses into what is termed an androgen non-responsive phenotype.

Multiple molecular mechanisms that could account for the development of resistance to ADT have been proposed (Feldman & Feldman 2001), which typically invoke the androgen receptor (AR) as a key mediator in the progression of PCa (Takeda \textit{et al.} 1996, Taplin & Balk 2004). Moreover, alterations of AR itself, which are either absent or at low frequency in the original
androgen-dependent state, result in an androgen-
hypersensitive situation where stimulation of PCa
growth occurs at castrate levels of androgens (Taplin &
Balk 2004). One of the AR alterations that occur is
AR mutation that results in promiscuous ligand
specificity (Veldscholte et al. 1990). Therefore, in
addition to its normal ligands, testosterone and
dihydrotestosterone (DHT), both androstenediol, a
precursor of testosterone, and estradiol can activate
the AR and stimulate the proliferation of LNCaP cells,
which have a mutated AR (Mizokami et al. 2004, Arnold et al.
2005). Testosterone and the more active
androgen DHT are important factors in PCa pro-
gression. These hormones are still present in PCa tissue
after ADT. Specifically, when PCa patients are treated
with ADT, serum testosterone and DHT decrease to
less than one-tenth of pretreatment levels (Labrie et al.
1985). However, testosterone and DHT in PCa tissue
are still present at 20–40% of pretreatment values
(Labrie et al. 1985, Belanger et al. 1989, Forti et al.
1989, Mizokami et al. 2004, Nishiyama et al. 2004,
Titus et al. 2005). These remaining androgens that are
still present post-therapy may continue to promote AR
activation and account for the observation that
combination therapy with a LHRH agonist, to block
androgen production, and an antiandrogen, to block
ligand binding to the AR, is more effective for PCa
treatment than either therapy alone (Labrie et al. 1985,

Testosterone and DHT in PCa tissue after medical or
surgical castration are synthesized locally in the
prostate from dehydroepiandrosterone (DHEA) of
adrenal origin (Labrie et al. 1985, Belanger et al.
1989, Forti et al. 1989, Mizokami et al. 2004,
Nishiyama et al. 2004, Titus et al. 2005). The metabolism from DHEA to DHT in peripheral target
tissues depends upon the level of expression of various
steroidogenic enzymes in the specific cell types of these
tissues (Labrie et al. 2005). Adrenal DHEA is
converted to testosterone by 17β-hydroxysteroid
dehydrogenase (17β-HSD) and 3β-HSD. Testosterone
is then converted to DHT by 5α-steroid reductase
(SRD5A) in the prostate (Andersson & Russell 1990,
Andersson et al. 1991, Labrie et al. 2005, Luu-The
et al. 2008). Currently, 2 types of 3β-HSD, 15 types of
17β-HSDs, and 3 types of SRD5A have been identified
and localized in various peripheral tissues, including
the prostate, with specific expression patterns in each
tissue (Luu-The et al. 2008, Uemura et al. 2008). For
example, 3β-HSD and type 5 17β-HSD were localized
in basal cells of alveoli, stromal cells, and endothelial
cells of blood vessels of the prostate (Pelletier et al.
2001). Fung et al. (2006) have observed increased
expression of AKR1C3 (type 5 17β-HSD) in PCa
tissue, while Stanbrough et al. (2006) confirmed that
ADT-resistant PCa and bone marrow metastases
expressed increased levels of multiple genes respon-
sible for androgen metabolism (HSD3B2, AKR1C3,
SRD5A1, AKR1C2, AKR1C1, and UGT2B15). These
studies provide support for the concept that PCa tissues
perform local biosynthesis of testosterone and
DHT resulting in activation of the AR (Labrie 1991).

It remains unclear; however, in which cell types
testosterone and DHT are converted from DHEA to
other androgens in PCa tissue, although the products
from DHEA and the relevant steroidogenic enzymes
are definitively present in the prostate. In this study,
we explored the hypothesis that PCa stromal cells
contribute to the biosynthesis of testosterone and
DHT in PCa. We demonstrated that testosterone and
DHT synthesized from DHEA in stromal cells
activated AR in PCa epithelial cells in a paracrine
fashion and thus contribute to the development of ADT
resistance in PCa.

Materials and methods

Isolation of stromal cells from prostate
carcinoma tissue

All studies were approved by the Institutional Review
Board. We obtained informed consent for experimental
use of all specimens obtained from prostate needle
biopsy or surgical procedure. The characteristics of
PCa patients are described in Table 1. Stromal cells
were isolated using a modification of a previously
described method (Krill et al. 1997). Briefly, small
pieces of PCa tissue were minced with scissors and
washed twice with PBS. The fragments were then
digested in 0.25% trypsin–EDTA (Invitrogen) for
30 min at 37 °C. After digestion, the dispersed stromal
cells were cultured in RPMI supplemented with
1% penicillin/streptomycin and 10% FCS (Sigma;
RPMI–10% FCS) on 6 cm dishes. Bone-derived

stromal cells 1 (BDSC-1) were obtained from the 11th rib of a 48-year-old man during left adrenalectomy for pheochromocytoma. BDSC-2 were obtained from the 11th rib of a 58-year-old man during left nephroureterectomy for localized ureteral cancer. These bone samples were cut into bone chips and further processed with a bone grinder (Lu et al. 2004). Bone chips were then cultured in RPMI–10% FCS like prostate-derived stromal cells.

Cell culture and cell proliferation assay
LNCaP cells were cultured in DMEM including phenol red–5% FCS (DMEM–5% FCS). Normal prostate-derived stromal cells, PrSC, commercially available (Cambrex, East Rutherford, NJ, USA) were cultured using SCGM BulletKit (Cambrex). Twenty-four hours after plating, 5 × 10^4 LNCaP cells were seeded on 12-well plates, aliquots of 3 × 10^4 stromal cells were plated onto Cell Culture Inserts (1.0 µm pore size 12-well format; Becton Dickinson, Franklin Lakes, NJ, USA) with DMEM, including phenol red–5% charcoal-stripped FCS (CCS; Hyclone, Logan, UT, USA) in 12-well plates for 24 h. Cells were then treated with DHEA (Sigma) and cultured for 4 days. As a positive control, LNCaP cells were treated with 0.1 nM DHT for 24 h without stromal cells. Medium and reagents were replaced every 2 days. At the end of the culture period, cells were trypsinized and counted in triplicate using a hemocytometer. All coculture studies were performed in DMEM–5% CCS. These experiments were performed at least twice to obtain reproducible data.

Coculture, transfection, and luciferase assay
To evaluate AR transcriptional activity, 24 h after plating 5 × 10^4 cells on 12-well plates in DMEM including phenol red–5% CCS, LNCaP cells were transfected using Lipofectamine transfection reaction (Invitrogen) using 0.4 µg luciferase reporter plasmid, pGL-5.8 PSAp, driven by a 5.8 kb PSA promoter including androgen-response elements (Mizokami et al. 2000). Twelve hours after transfection, LNCaP cells were cocultured with 5 × 10^4 stromal cells for 12 h, followed by the addition of indicated concentration of DHEA for 24 h. Cells were then harvested 24 h after the addition of reagents and lysed in luciferase lysis buffer (Promega). As a positive control, transfected LNCaP cells were treated with 0.1 nM DHT for 24 h without stromal cells. To block AR and SRD5A activity, we used 1 µM bicalutamide and 5 µM dutasteride (Dut; Nacalai Tesque, Kyoto, Japan). To knockdown AR expression in LNCaP cells by RNA interference, 5 × 10^4 LNCaP cells were transfected with 20 nM non-target (NT) siRNA, AR siRNA-1, or AR siRNA-2 (Invitrogen) using RNAiMAX (Invitrogen) for 12 h, and LNCaP cells were transfected with pGL3PASp-5.8 for 12 h. Then after changing the medium, transfected LNCaP cells were cocultured with or without PrSC. Consequently, cells were treated with or without 100 nM DHEA (+) for 24 h. As a positive control, cells were treated with 0.1 nM DHT for 24 h. For knockdown of AR expression in PrSC by RNA interference, we transfected 3 × 10^5 PrSC on a 6 cm dish with 50 nM RNAi or AR RNAi (5’-CAUAGUGACAACCCGAGCUUCUAUC-3’; Invitrogen) for 48 h with Lipofectamine RNAiMAX. Transfected cells were counted, and 5 × 10^4 siRNA-transfected PrSC were cocultured with 5 × 10^3 LNCaP cells transfected with pGL3PASp-5.8 12 h before coculture. Total RNA was extracted from the aliquot of PrSC transfected with AR siRNA. Knockdown of AR expression was confirmed by reverse transcription (RT)-PCR analysis. These experiments were performed at least twice to provide reproducible data.

Quantitative analysis of androgens in the medium by LC–ESI–MS/MS
Before harvesting cells, we collected the cultured medium and frozen it at −30 °C until LC–ESI–MS/MS was performed as previously described (Mizokami et al. 2004). For LC–ESI–MS/MS, 0.5 ml of the cultured medium was diluted with 0.5 ml distilled water, and then 5 ng androstenediol-2H4 (A-d4), 5 ng [16,16,17-2H3]-testosterone (100 pg), [17,16,16-2H3]-DHT (100 pg), [2,2,4,6,6,16,16-2H7]-DHEA (200 pg), [2,2,4,6-2H4]-adiol (100 pg) as internal standards were added to the individual samples. LC–ESI–MS/MS was performed using an API-4000 triple stage quadrupole mass spectrometer equipped with an ESI ion source (Applied Biosystems, Foster City, CA, USA) and an Agilent 1100 HPLC system (Agilent Technologies, Santa Clara, CA, USA) with HTC PAL auto-sampler (CTC Analytical, Zwingen, Switzerland). The assay was validated to ensure that the result was within the 20% range of accuracy and precision. We confirmed that endogenous DHEA, adiol, adione, testosterone, and DHT in DMEM–5% CCS were below detectable methods.

RNA extraction and RT-PCR
Twenty-four hours after plating, 5 × 10^4 LNCaP cells or stromal cells were treated with or without 10^{-8} M DHT for 24 h at which time total RNA was purified with RNeasy mini kit (Qiagen). cDNA was made by
RT of 200 ng each total RNA using ThermoScript RT-PCR system (Invitrogen). Each cDNA sample was amplified with ExTaq (Takara, Otsu, Japan). The sense and antisense primers used and RT-PCR conditions are shown in Table 2. The amplified PCR products were visualized using electrophoresis on a 1.5% agarose gel. For quantification of mRNA expression, real-time PCR was performed according to the manufacturer’s instructions and using the LightCycler TaqMan Master Solution, PCR primers, and Universal probe (Roche Applied Science). The gene expression in each sample was quantified as the yield of the target gene relative to that of the glyceraldehyde-3-phosphate dehydrogenase (GAPDH) gene.

Statistical analysis

Student’s t-test, for bivariate comparisons, or ANOVA with Fisher’s least significant difference post hoc test, for multivariate comparisons, were used to determine the statistical significance of differences of proliferation and luciferase assays. *P < 0.05 was considered statistically significant.

Results

Effect of DHT and DHEA on LNCaP cells in the presence of stromal cells

In order to investigate AR activity, we transfected LNCaP cells with a luciferase expression plasmid driven by the prostate-specific antigen (PSA) promoter, pGL3PSAp-5.8, and performed luciferase assay because this method is simple, effective, and highly sensitive compared with ELISA for PSA protein and quantification of mRNA by RT-PCR (Mizokami et al. 2004). When LNCaP cells transfected with pGL3PSAp-5.8 were treated with DHEA, PSA promoter activity was induced in a dose-dependent manner as previously described (Fig. 1A; Mizokami et al. 2004). However, high concentrations of DHEA were required for DHEA-mediated induction of the PSA promoter. We cotransfected LNCaP cells with AR siRNA expression plasmids and pGL-5.8PSAp and treated cells with DHEA in the absence and presence of PrSC. Transfection of LNCaP cells with AR siRNA resulted in >90% decrease in AR expression (Fig. 1D). Knockdown of AR expression in LNCaP cells diminished DHEA-induced PSA promoter activation in both the absence and presence of PrSC (Fig. 1D). This observation suggests that LNCaP AR expression is required for DHEA-mediated PSA activation both in LNCaP cells alone and the increase of DHEA-mediated activation of the PSA promoter in the presence of PrSC (as observed in Fig. 1A). To determine whether DHEA also mediates its effects on LNCaP cells through a requirement for AR in the PrSC, we knocked down AR expression in PrSC using AR shRNA, which resulted in decreasing AR expression >90% (Fig. 1E). Coculture of PrSC transfected with AR shRNA and LNCaP had no impact on DHEA-induced PSA promoter compared with coculture of PrSC transfected with NT control shRNA. These results indicate that DHEA action was increased in the presence of PrSC by a mechanism other than via AR in PrSC cells, such as paracrine factors produced in PrSC from DHEA metabolites (Fig. 1E right).

Effect of PCa-derived stromal cells on LNCaP cells

To further investigate whether the ability of PrSC to promote androgen activity in the LNCaP cells was prostate specific, we examined stromal cells from different tissues. Coculture of LNCaP cells with human bone marrow-derived stromal cells and lung-derived stromal cells enhanced DHEA-induced PSA promoter activity, although these effects were somewhat lower than with PrSC (Fig. 2A).

We next investigated whether PCa-derived stromal cells (PCaSC) could regulate DHEA-stimulatory...
effects on PSA promoter in LNCaP cells. We performed primary cultures of several PCaSCs from PCa tissue obtained by prostate needle biopsy for diagnosis (pathology and stage of patients are described in Table 1). All PCaSCs expressed vimentin and keratinocyte growth factor, thus confirming their stromal origin (Fig. 2B). All PCaSCs increased DHEA-induced PSA promoter activity. PCaSC-1, -2, -5, -8, and -9 stimulated greater DHEA-induced PSA promoter activity than the PrSC (Fig. 3C). Since PCa often metastasizes to bones, we also cocultured LNCaP cells with BDSC-1 and -2. To confirm bone origin of the BDSC, we examined for expression of osteoblast factors. RT-PCR confirmed that core-binding factor α1, osteopontin, and osteocalcin were expressed in both BDSC-1 and -2, indicating that they were of bone origin (Fig. 2B). Both BDSCs increased PSA promoter activity induced by DHEA at a level 5.4–7.6-fold higher than observed with PrSC (Fig. 2C).

We next investigated in further detail how coculture with PCaSCs affected the proliferation of LNCaP cells in the presence of DHEA. When LNCaP cells were cultured without stromal cells, more than 10 nM DHEA was necessary to stimulate cell proliferation (Fig. 1B). Furthermore, when LNCaP cells were cocultured with PCaSC-5, -8, or -9 cells were seeded on the upper chamber. Twelve hours later, cells were treated with increasing concentrations of DHEA for 4 days and counted. Medium was changed every 2 days, and DHEA was added to medium. These coculture experiments were performed at least twice with reproducible data. The data are presented as the mean ± s.e. of triplicate measurements.

Figure 2 Effect of stromal cells from different tissues and PCa tissues on DHEA and DHT-induced PSA promoter activity and proliferation. (A) Effect of stromal cells from different tissues on DHEA and DHT-induced PSA promoter activity. Stromal cells from different tissues, PrSC, HMSC, and HLFa, were cocultured with LNCaP cells transfected with pGL3PSAp-5.8 and treated with 100 nM DHEA for 24 h, and luciferase activities were measured. (B) Confirmation of stromal cells from different PCa patients and the normal rib bone. Expression of vimentin and KGF was observed in prostate-derived stromal cells by RT-PCR. Expression of cbfa1 and osteopontin (OPN) was also observed in BDSC-1 and BDSC-2 by RT-PCR. (C) Effect of stromal cells from different PCa patients and the normal rib bone on PSA promoter activity. Columns indicate the relative acceleration ratio compared with 100 nM DHEA alone in the absence of stromal cells, and the number above each column represents relative induction ratio compared with PrSC. (D) Effect of different PCaSCs on LNCaP cell proliferation. Twenty-four hours after 3×10^4 LNCaP cells were cultured on the lower chamber, PCaSC-5, -8, or -9 cells were seeded on the upper chamber. Twelve hours later, cells were treated with increasing concentrations of DHEA for 4 days and counted. Medium was changed every 2 days, and DHEA was added to medium. These coculture experiments were performed at least twice with reproducible data. The data are presented as the mean ± s.e. of triplicate measurements.
Androgen concentration in medium after coculture with stromal cells

We hypothesized that the change of AR activity in the LNCaP cells induced by stromal cells in the presence of DHT and DHEA was influenced by the change in metabolism of androgens caused by stromal cells. To test this hypothesis, we examined the change in the concentrations of various androgens in the culture medium following coculture with stromal cells. After transfection with pGL-5.8PSAp, LNCaP cells cocultured with PrSC or PCaSC-8 were treated with 100 nM DHEA. When LNCaP cells were cocultured with PrSC or PCaSC-8 in the presence of DHEA, PSA promoter activity was activated more than 2.5 and 8.0 times when LNCaP cells were cultured alone respectively (Fig. 3A).

In the absence of DHEA, we could not detect testosterone and DHT in LNCaP and stromal cells using LC–MS/MS (data not shown). When LNCaP cells were cultured alone, the addition of 100 nM DHEA resulted in media concentrations of 75.3 pM testosterone and 12.4 pM DHT in 24 h (Fig. 3B upper graphs). The addition of PrSC increased the concentration of testosterone and DHT in the medium to 104.6 and 23.6 pM 24 h after the addition of 100 nM DHEA respectively (Fig. 3B upper graphs). Moreover, coculture of LNCaP cells with PCaSC-8 increased testosterone and DHT to 522.6 and 128.9 pM 24 h after the addition of DHEA respectively (Fig. 3B upper graphs). The degree of increase in testosterone and DHT by coculture corresponded with DHEA-induced PSA promoter activity in the presence or absence of stromal cells as observed in the previous experiments.

To examine how DHEA was metabolized to testosterone in this culture system, we measured the concentration of intermediate metabolites, androstenedione (adione), and androstenediol (adiol) in the medium (Fig. 3C lower graphs). LNCaP monoculture contained 6456 pM adione at 24 h from the addition of 100 nM DHEA, whereas in the presence of stromal cells it was ~9500 pM. This finding indicates that there was more 3β-HSDs activity in the coculture as opposed to the LNCaP monoculture (Fig. 3C lower graphs). We also found that the concentration of adiol in medium from the LNCaP and PrSC coculture was reduced compared with LNCaP monoculture. In contrast, the concentration of adiol synthesized in the PCaSC-8 and LNCaP coculture in the presence of DHEA was increased to 4374 pM at 24 h. These data indicate that DHEA is converted into testosterone mainly via adione in the presence of PrSC and via both adione and adiol in the presence of PCaSC-8.
Expression of androgen biosynthesis enzymes

Several enzymes are involved in the conversion pathway of DHEA to testosterone and DHT. Accordingly, we quantified mRNA expression level of AR and androgen biosynthesis enzymes in LNCaP, PrSC, and BDSC (Fig. 4). Real-time PCR analysis revealed that AR expression level of all stromal cells was less than ten times that of the levels in LNCaP cells. Types 1 and 2 3β-HSD, which catalyzes the transformation of DHEA into adione and adiol to testosterone, were expressed in LNCaP cells and barely detectable in all stromal cells. Stromal cells expressed types 2 and 4 17β-HSD at relatively high level. The level of expression of types 2 and 4 17β-HSD, which catalyzes the transformation of testosterone into adione, was different among stromal cells. Type 3 17β-HSD, which is mainly expressed in the testes and catalyzes the transformation of adione into testosterone (Geissler et al. 1994), was expressed in LNCaP cells and all stromal cells at a very low level. The expression

Figure 4 Real-time RT-PCR analysis of AR and androgen biosynthesis enzymes mRNA in LNCaP cells and stromal cells. Expression of AR, various HSD17s, HSD3B1 and 2, SRD5As, and AKR1C2 mRNA in various stromal cells was confirmed using real-time RT-PCR analysis. 1, LNCaP cells treated without androgen for 24 h in DMEM–5% CCS; 2, LNCaP cells treated with 10 nM DHT for 24 h; 3, PC-3 cells; 4, DU145 cells; 5, PrSC; 6, PCaSC-1; 7, PCaSC-2; 8, PCaSC-5; 9, PCaSC-6; 10, PCaSC-7; 11, PCaSC-8; 12, PCaSC-9; 13, BDSC-1; 14, BDSC-2.
level of type 5 17β-HSD (aldo–keto reductase, AKR1C3), which is believed to catalyze the transformation of DHEA and adione into adiol and testosterone respectively (Dufort et al. 1999), is expressed at different levels among stromal cells, although LNCaP cells show a low level of expression. The expression level of type 5 17β-HSD of PrSC and PCaSC-8 was not correlated with DHEA-induced PSA promoter activity in the presence of PrSC or PCaSC-8.

Testosterone is converted to DHT by SRD5A in the prostate. Until now, three types of SRD5A were identified (Andersson & Russell 1990, Andersson et al. 1991, Labrie et al. 2005, Luu-The et al. 2008, Uemura et al. 2008). Type 1 SRD5A was ubiquitously expressed in all cells compared with type 2 SRD5A. Type 3 SRD5A, which has been recently identified (Uemura et al. 2008), was expressed in LNCaP cells at a relatively high level and well expressed in all stromal cells compared with types 1 and 2 SRD5A. AKR1C2, which catalyzes the transformation from DHT into the inactive form androstane-3α, 17β-diol (androstane-diol), was expressed in all cells at a relatively low level, especially in LNCaP cells.

**Type 5 17β-HSD does not contribute to testosterone biosynthesis in PrSC**

Dufort et al. (1999) reported that type 5 17β-HSD may be involved in DHEA metabolism in stromal cells. This is supported by our findings that several stromal cells, including PCaSC-8, synthesized large amounts of adiol from DHEA (Fig. 3C). However, since expression levels of type 5 17β-HSD mRNA in stromal cells were not correlated with PSA activity as described in Fig. 2C, we focused on the activity (as opposed to expression level) of type 5 17β-HSD. In order to inhibit type 5 17β-HSD activity, we used naproxen, which is a non-steroidal anti-inflammatory drug and an AKR1C3 inhibitor (Gobec et al. 2005). Naproxen did not inhibit PCaSC-8-induced DHEA activity in the coculture of LNCaP and PCaSC-8 cells (Fig. 5B). To further confirm these data, we cocultured LNCaP cells with PCaSC-8 in which type 5 17β-HSD was knocked down using shRNA. Knockdown of type 5 17β-HSD expression in PCaSC-8 did not repress DHEA-induced PSA promoter activity (Fig. 5C). These data suggest that type 5 17β-HSD does not significantly contribute to the conversion of adione into testosterone in PCaSC.

**Figure 5** Effect of type 5 17β-HSD on DHEA-induced PSA promoter activity. (A) Effect of HSD17B-5 inhibitor, naproxen, and HSD17B-5 shRNA on DHEA-induced PSA promoter activity. After 5 × 10⁴ LNCaP cells were transfected with 0.4 μg pGL-5.8PSAp for 12 h, the cells were cocultured with 0 or 5 × 10⁴ PCaSC-8 cells for 12 h. Consequently, both cells were treated with 100 nM DHEA in the absence or presence of 5 μM naproxen for 24 h, and then the absolute luciferase activities were measured. (B) Knockdown of HSD17B-5 mRNA and PSA promoter activity. After PCaSC-8 was transfected with 50 nM HSD17B-5 siRNA for 48 h, RNA was purified and subjected to RT-PCR of HSD17B-5 mRNA. As a negative control, 100 nM non-targeting (NT) siRNA was also transfected. LNCaP cells transfected with pGL-5.8PSAp were cocultured with siRNA-transfected PCaSC-8. Then, LNCaP and PCaSC-8 cells were treated with 100 nM DHEA for 24 h and luciferase activities were measured. These coculture experiments were performed at least twice with reproducible data. The data are presented as the mean ± s.d. of triplicate measurements. NS means not statistically significant difference.
Effect of a dual 5α-reductase inhibitor on DHT biosynthesis in stromal cells

Since SRD5A types 1 and 3 are expressed in all stromal cells and DHT is synthesized from DHEA in stromal cells, we investigated whether the dual 5α-reductase inhibitor, Dut, could block DHEA-induced PSA promoter activity in the presence of stromal cells. Coculture of LNCaP cells with PCaSC-8 or -9 increased DHEA-induced PSA promoter activity to 10- or 30-fold respectively (Fig. 6A). Five micromolar Dut significantly inhibited PSA promoter activity induced by 100 nM DHEA as well as 0.1 nM testosterone, regardless of the presence of PCaSC-8 or -9. Simultaneously, we investigated how testosterone was metabolized in LNCaP monoculture by Dut and how DHEA was metabolized to other androgens by PCaSC-8 and -9 in the presence of Dut. When LNCaP cells were treated with testosterone in the presence of 5 μM Dut, there was minimal production of DHT, and the metabolism of testosterone was reduced in the medium after 24 h (Fig. 6B). Dut inhibited conversion of DHEA to DHT in the LNCaP and PCaSC-8 or -9 coculture (Fig. 6C). Dut also inhibited testosterone biosynthesis from DHEA in LNCaP cells by ~80% at 24 h. This inhibition of testosterone biosynthesis was
also observed in coculture with PCaSC-8 or -9 by ~75 and 66% respectively (Fig. 6C). We also measured the concentration of adione and adiol 24 h after DHEA and Dut treatments (Fig. 6D). The concentration of adione was decreased by Dut in accordance with the decrease in the concentration of testosterone. In contrast, the concentration of adiol was not changed by Dut regardless of PCaSCs.

**Comparison of androgen concentrations on coculture with those on PCaSC-8 and -9 monoculture**

The androgen concentrations measured in Fig. 6C and D were totals of androgens metabolized by LNCaP cells and PCaSC-8 or -9. Therefore, we measured the androgen concentrations in medium of monoculture cells treated with DHEA for 24 h (Fig. 6E and F). The sum of testosterone and DHT concentrations from the monocultures of the LNCaP cells and the PCaSCs was less than testosterone and DHT concentrations in coculture without Dut (compare Fig. 6E with C). This suggests that the presence of the two cell types in the coculture stimulates testosterone and DHT synthesis in a synergistic fashion. On the other hand, LNCaP cells produced much higher levels of adione in monoculture than either PCaSC line (Fig. 6F). The total adione in the coculture approximates that of the LNCaP monoculture (compare Fig. 6D with F), suggesting that, in coculture, the total adione may be primarily due to production by 3β-HSD in LNCaP cells, although this has not been definitively demonstrated. The adiol levels in coculture with PCaSC-8 or -9 were more than the sum of adiol produced from DHEA by the monocultures (compare Fig. 6D with F). This suggests that the presence of the two cell types in the coculture stimulates adiol synthesis in a synergistic fashion.

We also examined the effect of Dut on the androgen levels in coculture versus monocultures. Five micromolar Dut inhibited DHT synthesis from testosterone in LNCaP, PCaSC-8, and PCaSC-9 mononcultures and also adione synthesis from DHEA in LNCaP monoculture. However, Dut did not inhibit adione synthesis in PCaSC-8 and -9 (Fig. 6F). This result indicates that reduction of testosterone concentration observed in coculture in the presence of Dut is due to inhibition of adione synthesis by Dut in LNCaP cells, but not PCaSCs.

**Discussion**

The present study shows that PrSC can increase AR activity induced by the adrenal precursor DHEA in androgen-sensitive PCa cells and stimulate the proliferation of PCa cells. Furthermore, PCaSC and BDSC induce greater androgen activity than PrSC or lung-derived stromal cells. The physiological concentration of serum DHEA is between 3 and 15 nM, although that of DHEA-sulfate (DHEA-S) ranges between 1 and 10 μM. This concentration of DHEA did not stimulate the proliferation during mononculture of LNCaP cells. We also confirmed that 10 μM DHEA-S had almost no ability to activate AR even in the presence of stromal cells (data not shown), thus suggesting that the LNCaP and stromal cells studied have little steroid sulfatase activity.

Our results show that physiological concentrations of DHEA stimulate the proliferation of LNCaP cells in the presence of stromal cells, especially cancer-derived stromal cells. The present data strongly suggest that biosynthesis of testosterone and DHT in stromal cells mediates paracrine stimulation of PCa cells. This activity could readily contribute to androgen deprivation-refractory PCa after ADT. Recently, Arnold et al. (2008) have described a similar study using coculture of LAPC4 androgen-sensitive PCa cells with stromal cells. According to their study, PCa-derived stromal cells also increased PSA mRNA expression induced by DHEA. However, they did not identify that the proliferation of LAPC4 cells was stimulated by DHEA in the presence of PCa-derived stromal cells in contrast to the proliferation of LNCaP cells in our study. The difference between our study and their study may be due to a difference in sensitivity for androgens between LNCaP and LAPC4.

Several mechanisms explaining why advanced PCa relapses during ADT have been considered (Feldman & Feldman 2001, Schroder 2008). AR amplification, action of cytokines on the AR, induction of AR coactivators, or STAT-3 activation (Fujimoto et al. 2001, Harada et al. 2001, Chen et al. 2004) all can cause an androgen-hypersensitive state in PCa. It has also been shown that coculture of stromal cells with PCa-derived epithelial cells enhanced AR activity via recruitment of coregulators (Cano et al. 2007). Pathways that are involved in the development of treatment-resistant PCa are also related to the microenvironment surrounding cancer cells. In fact, PCa–stroma interactions play an important key factor for prostate development and carcinogenesis (Cunha et al. 2004). Increased expression of chemokines, cytokines, and growth factors from stromal cells drives PCa cells to a more invasive and malignant state (Sung & Chung 2002, Kaminski et al. 2006, Le et al. 2006). Accordingly, alterations in the stromal microenvironment as well as PCa cells themselves cooperate to promote malignant transformation of PCa.
It is very likely that residual androgens in PCa tissue are involved in the progression of PCa that has become androgen hypersensitive. Our data indicate that the adrenal androgen precursor DHEA acts as precursor for synthesis of residual androgens in PCa tissues. Recently, many physicians have adopted combined androgen blockade using an LHRH agonist and an antiandrogen as initial treatment for advanced PCa. However, metastatic PCa relapses and serum PSA values increase a few years later. Ketoconazole that inhibits the synthesis of adrenal DHEA is often used for HRPC in West European countries and has a response rate of about 60%, but the response is of short duration. Furthermore, in phase II studies using the CYP17A inhibitor abiraterone, which blocks DHEA synthesis, PSA declines of >50% in 12 out of 21 (57%) patients have been observed (Attard et al. 2008), although cessation of the antiandrogen, by itself, could have caused a significant effect on PSA. These results suggest that adrenal DHEA contributes to >50% of relapses of advanced metastatic PCa.

Even after ADT, DHT remains in the PCa tissue at 20–40% of untreated prostate tissue, although serum DHT levels decrease to <10% after ADT (Labrie et al. 1985, 1993, Mizokami et al. 2004, Nishiyama et al. 2004). Mohler et al. (2004) demonstrated that recurrent PCa tissue retains testosterone at around 50% of benign prostate tissue. Recently, Montgomery et al. (2008) has demonstrated that testosterone levels within metastases from anorchid men were significantly higher than levels within primary PCa from untreated eugonadal men. These reports indicate that testosterone and DHT accumulate in PCa tissue and metastatic lesions after ADT. These data as well as the presence of steroidogenic enzymes in PCa tissue strongly suggest that testosterone is synthesized from adrenal DHEA not only in the testes but also in PCa tissue and metastatic lesions by ‘intracrine synthesis’ (Labrie et al. 1985, 1993, 2004).

The mechanisms through which testosterone and DHT are synthesized in PCa tissue and how they contribute to PCa progression are unclear. Our data indicate that stromal cells promote androgen production in PCa either directly or through simulation of PCa epithelial cell-mediated production of androgens. The PSA promoter activity induced by DHEA was only moderate in LNCaP monocultures. However, coculture with stromal cells, especially PCaSCs, strongly activated PSA promoter activity induced by DHEA. Although our results are consistent with Arnold et al. (2008) observation that testosterone synthesized from DHEA in PCa-derived stromal cells contributed to PSA induction in LAPC4, we extended these studies further to elucidate which pathways were involved in testosterone synthesis. Specifically, we identified that the increased level of DHEA-induced AR activity by stromal cells was dependent on the synthesized level of testosterone and DHT achieved by coculture. (Figs 3 and 6). Furthermore, the ability and the predominant pathways (via adiol and/or via adione) of testosterone biosynthesis from DHEA were dependent on stromal cells. These results suggest that enzymatic activities, which catalyze conversion of DHEA to testosterone or DHT via adiol or adione, differ among stromal cells and coordinately with cancer cells.

When we examined the expression of androgen biosynthesis enzymes, expression pattern was different among each of stromal cells. Furthermore, the expression pattern of type 5 17β-HSD in stromal cells, whose expression has been reported to be increased in PCa (Fung et al. 2006), did not correlate with increase in DHEA-induced PSA promoter activity by stromal cells. This discrepancy may be due to several reasons: 1) expression level of androgen biosynthesis enzymes mRNA does not always reflect its enzymatic activity; 2) total activity of all 17β-HSDs may be important for the global conversion of DHEA to adiol or adione to testosterone; and 3) recently, type 15 17β-HSD has been proposed to convert adione to testosterone and thus may impact the overall response (Luu-The et al. 2008).

DHT is usually synthesized from testosterone by SRD5A1 and 2 in the prostate. Although SRD5A2 is predominantly expressed in the normal prostate, recent evidence shows that SRD5A1 is highly expressed in PCa and HRPC, whereas SRD5A2 is not highly expressed (Thomas et al. 2008). Consistent with this finding, we also observed that SRD5A1 was highly expressed in LNCaP cells and in all stromal cells. Uemura et al. (2008) discovered SRD5A3 in HRPC. SRD5A3 is predominantly expressed in HRPC, but not in androgen-sensitive PCa. We observed that both LNCaP cells and PCaSC from PCa patients expressed SRD5A3 mRNA, and that Dut almost completely blocked PSA promoter activity induced by testosterone and DHEA in the presence or absence of stromal cells. Dut may inhibit SRD5A3 activity as well as SRD5A1 and SRD5A2 activity. Interestingly, when LNCaP cells were treated with DHEA regardless of the presence or absence of stromal cells, Dut inhibited not only DHT biosynthesis but also testosterone and adione biosynthesis from DHEA in LNCaP cells. However, inhibition of adione biosynthesis from DHEA by Dut was not observed in PCaSC-8 and -9 (Fig. 6F). It is not clear why Dut inhibited adione synthesis only in
LNCaP cells. Recently, Lazier et al. (2004) have demonstrated that Dut not only inhibits the conversion from testosterone to DHT but also acted as an antiandrogen. We also confirmed that Dut inhibited PSA promoter activity induced by DHT in LNCaP cells (data not shown). Taken together, Dut may have a variety of inhibitory functions on androgen biosynthesis and AR action.

On the basis of our data and previous reports, we propose an interactive model for the interaction between PCa cells and the surrounding stromal cells (Fig. 7). The proliferation of PCa is highly dependent upon testosterone and DHT secreted from the testes, the testosterone of testicular origin adds to the testosterone made locally from DHEA (Labrie et al. 2005). Although ADT induces apoptosis of many PCa epithelial cells, stromal cells surrounding PCa cells can still survive. Then oncogenes, cytokines, and growth factors may affect survival and progression, especially when only partial androgen blockade or monotherapy is used. On the other hand, PCaSC can synthesize testosterone and DHT from DHEA coordinately with cancer cells and secrete them to the surrounding area in a paracrine fashion. Surviving PCa cells receive an androgenic supply from stromal cells, and progression of the cancer continues. However, we cannot eliminate that some growth factors or cytokines induced by DHEA in either stromal or epithelial cells affect LNCaP proliferation independent of AR.

Figure 7 Mechanism of how DHEA contributes to androgen therapy non-responsive PCa. Prior to androgen deprivation therapy (ADT), testosterone from the testes plays a major role in the androgen activity in the prostate, whereas the adrenal androgen DHEA plays a minor role. After ADT, in addition to the growth factors and cytokines from PCa-derived stromal cells that stimulate the proliferation of PCa, residual PCa cells become androgen hypersensitive through various mechanisms and simultaneously PCa-derived stromal cells synthesize testosterone, DHT, and precursors from DHEA coordinately. These synthesized androgens induce AR activity and stimulate the progression of PCa in a paracrine fashion.
In conclusion, we have demonstrated that the concentration of testosterone and DHT in PCa tissue is higher than in serum after ADT. This results from biosynthesis of testosterone from DHEA in PCa-derived tissues. It is possible that both stromal and epithelial cells may contribute to the conversion of DHEA to testosterone. Our coculture assay system is extremely useful for measuring total DHEA activity, which results in AR activation in PCa and stromal cells. Such data could support the development of new drugs to inhibit biosynthesis of androgens. Moreover, using this assay system, there may be a possibility of predicting relapse and the time of relapse at diagnosis of advanced PCa, depending upon the level of steroidogenic enzyme expression. In the present study, we used stromal cells from high-grade PCa tissue ( Gleason 7, 8, and 9). It would be interesting if we could culture stromal cells from low-grade PCa tissue and perform the same study; however, these were not readily available for our studies. Additional studies are needed to assess which enzymes are the most involved in the biosynthesis of androgens in PCa tissue. The present data also indicate that monotherapy of PCa with medical or surgical castration alone or an antiandrogen alone is an insufficient treatment for PCa at any stage of the disease, due to the major importance of the local biosynthesis of androgens from DHEA.
