Abstract

Organ of Zuckerkandl paragangliomas (PGLs) are rare neuroendocrine tumors that are derived from chromaffin cells located around the origin of the inferior mesenteric artery extending to the level of the aortic bifurcation. Mutations in the genes encoding succinate dehydrogenase subunits (SDH) B, C, and D (SDHx) have been associated with PGLs, but their contribution to PGLs of the organ of Zuckerkandl is not known. We aimed to describe the clinical presentation of patients with PGLs of the organ of Zuckerkandl and investigate the prevalence of SDHx mutations and other genetic defects among them. The clinical characteristics of 14 patients with PGL of the organ of Zuckerkandl were analyzed retrospectively; their DNA was tested for SDHx mutations and deletions. Eleven out of 14 (79%) patients with PGLs of the organ of Zuckerkandl were found to have mutations in the SDHB (9) or SDHD (2) genes; one patient was found to have the Carney–Stratakis syndrome (CSS), and his PGL was discovered during surgery for gastrointestinal stromal tumor. Our results show that SDHx mutations are prevalent in pediatric and adult PGLs of the organ of Zuckerkandl. Patients with PGLs of the organ of Zuckerkandl should be screened for SDHx mutations and the CSS; in addition, asymptomatic carriers of an SDHx mutation among the relatives of affected patients may benefit from tumor screening for early PGL detection.

Endocrine-Related Cancer (2010) 17 581–588

Introduction

The organ of Zuckerkandl consists of extra-adrenal chromaffin cells located just below the origin of the inferior mesenteric artery and above the bifurcation of the aorta. This collection of paraganglia was first described by Hungarian anatomist and surgeon, Emil Zuckerkandl, who initially named them Nebenorgane (auxiliary organs; Ober 1983). The chromaffin cells that comprise the organ of Zuckerkandl originate from the same neural crest progenitor cells that give rise to the adrenal medulla. While these structures normally degenerate and involute by adolescence, small clusters of chromaffin cells remain that can serve as sites of future tumor development. At least 135 cases of paragangliomas (PGLs) of the organ of Zuckerkandl have been reported in the literature, but their association with specific mutations and/or genetic syndromes has not been described (Subramanian & Maker 2006).

Germline mutations in the genes encoding subunits B, C, and D of succinate dehydrogenase (SDH), the
mitochondrial complex II, have been associated with
the development of PGLs (Baysal et al. 2000, Astuti
et al. 2001, 2003, Gimenez-Roqueplo et al. 2003,
Brouwers et al. 2006, Ghayee et al. 2009). The SDHB,
SDHC, and SDHD genes encode mitochondrial
proteins which serve as tumor suppressors, and loss-
of-function mutations in these genes are linked to
formation of PGLs (Gottlieb & Tomlinson 2005). The
SDH enzyme is involved in cellular energy metabolism
through the tricarboxylic acid cycle, the oxidative
phosphorylation, and the electron transport chain
(Gottlieb & Tomlinson 2005). Although the mechanism
that explains the link between mito-
chondrial dysfunction and tumor formation remains
unknown, it is thought to be linked to an increase in
reactive oxygen species and/or the activation of the
hypoxia pathway or apoptosis (Eng et al. 2003,
Gottlieb & Tomlinson 2005, Benn & Robinson 2006,
Favier et al. 2009). The development of metastatic
disease may be related to up-regulation of angiogen-
esis; however, the exact mechanism remains to be
elucidated (Favier et al. 2002).

While an association with mutations in SDHB and
SDHD genes has been found in patients with mediastinal PGLs, a specific analysis of SDH
mutations in patients with Zuckerkandl organ PGLs
has not been performed to date. SDHD gene mutations
are specifically associated with head and neck PGLs
and much less frequently with malignant PGLs (Baysal
et al. 2000, Benn et al. 2006, Havekes et al. 2007,
Timmers et al. 2008). Mutations in the SDH gene are
associated with a high rate of malignancy and
aggressive disease; among patients with metastatic
PGLs, the frequency of SDHB mutations is between 30
and 83% (Gimenez-Roqueplo et al. 2003, Neumann
SDHB mutations have also been associated with
shorter survival (Amar et al. 2007). Tumors classified
as extra-adrenal abdominal PGLs (including a group-
ing of paraaortic/pericaval, bladder, remnants of the
organ of Zuckerkandl, perirenal, retroperitoneal, and
periadrenal) are associated with mutations in both
SDHB and SDHD genes (Benn et al. 2006). Anecdotal
reports have described six patients with tumors of the
organ of Zuckerkandl and SDHD (2) or SDHB (4)
mutations; however, to our knowledge this is the
first series with a specific focus on tumors of this
anatomic site (Gimenez-Roqueplo et al. 2003,
Donahue et al. 2008).

From an initial observation of two patients with
Zuckerkandl organ tumors who had SDHx mutations,
we searched our clinical database for other patients
with tumors involving this organ; we then tested the
DNA of these patients retrospectively for mutations in
SDHx. Three of the patients had mutations in SDHx
identified prior to their evaluation at our institution.
In the present study we report in detail the clinical
characteristics, biochemical phenotype, and clinical
course of 14 patients with Zuckerkandl organ tumors
seen at the National Institutes of Health (NIH) and the
University of Texas M.D. Anderson Cancer Center
over the past 20 years; in these patients, we examined
the frequency of SDHx mutations.

Materials and methods
Subjects of protocol
Fourteen patients with primary PGLs of the organ
of Zuckerkandl with a median age at diagnosis of 22.5
years (range 9–71) seen at the NIH, University of
Texas M.D. Anderson Cancer Center and Dana-Farber
Cancer Institute between 1989 and 2009 are presented
in this study. A retrospective chart analysis was
performed in order to identify patients with
Zuckerkandl organ PGLs via review of abdominal
computed tomography (CT) scans and analysis of
operative and pathology reports. We reviewed radi-
ological scans from all the cases and included only those
tumors defined by the radiologist to be consistent with
the specific anatomic localization of the Zuckerkandl
organ. The patients were followed up for an average of
8 years. Initial patient symptoms, biochemical pheno-
type, details of primary tumor, and patient outcome
were recorded. The presence of disease in sites where
chromaffin cells are not normally present, i.e. disease
in an extra-paraganglionic site (lymph nodes, bone,
liver, and lung), was used to define metastatic disease
differentiated from multiple sites of disease
(Gimenez-Roqueplo et al. 2008). Consent was
obtained from each patient after full explanation of
the purpose and nature of all procedures used. The
investigation was approved by the NICHD IRB and the
M.D. Anderson Cancer Center IRB.

Genetic studies
Three patients were known to harbor SDHx mutations
prior to their evaluation at the NIH. For those patients
without prior studies, genetic testing of germline DNA
for mutations in SDHB, C, and D genes was performed.
Blood samples for SDHx mutation analysis were
collected prospectively for purposes of genetic testing.
Genomic DNA was extracted from whole blood as
described previously. The four exons of SDHD, eight
exons of SDHB, and six exons of SDHC were amplified
and sequenced by PCR based bidirectional sequencing
by Mayo Medical Laboratories, Rochester, MN, USA or by the Division of Molecular Diagnostics at the University of Pittsburgh Medical Center, as described previously (Brouwers et al. 2006). Deletion testing was performed using a combination of multiplex ligation-dependant probe amplification and Luminex FlexMap Technologies (Monico et al. 2007).

Hormone assays

Plasma catecholamines and metanephrines, and urinary catecholamines and metanephrines were measured using standard HPLC assays, as described previously, at the NIH Clinical Center and Mayo Medical Laboratories (Eisenhofer et al. 1986, Lenders et al. 1993).

Results

Patient characteristics are presented in Table 1. The median age of the nine males and five females at diagnosis was 22.5 years (range 9–71). Eleven out of 14 (79%) patients with organ of Zuckerkandl PGLs were found to have mutations in the SDHB (9) or SDHD (2) genes. Four of these represent nonsense mutations, two missense mutations, two deletions, two frameshift and one splice site mutation. No mutations were found in three patients. Details of the mutations are presented in Table 1; two of the mutations represent novel mutations, SDHB p.Arg38ProfsX40 and SDHB Tyr61X, the remaining six are reported previously (Baysal et al. 2000, Brouwers et al. 2006, Timmers et al. 2007, Pasini et al. 2008, Solis et al. 2009). Three of the 14 patients had a first degree relative with a history of pheochromocytoma or PGL. None of the 14 patients were related to one another.

Eight out of 14 (57%) patients had signs and symptoms related to catecholamine excess at the time of diagnosis. Results obtained from imaging studies used to detect tumor are presented in Table 1. In all 14 patients, CT scans were positive for visualization of Zuckerkandl organ tumor. 123I-metaiodobenzylguanidine (123I-MIBG) scans were able to detect tumors in eight out of nine cases, and T2 magnetic resonance imaging was positive in all eight patients in whom it was used. Four out of 14 (30%) patients presented with the organ of Zuckerkandl PGL as their only primary tumor. While eight patients presented with metastatic disease, not all of these had the organ of Zuckerkandl PGL at the time of presentation. Seven out of 14 (50%) patients who had organ of Zuckerkandl tumors as part of their initial presentation also had multiple primary tumors or metastatic disease at initial diagnosis. Two out of 14 (14%) patients were identified to have the organ of Zuckerkandl PGL as an additional site of disease on long-term follow-up. One patient was diagnosed with the Carney–Stratakis syndrome (CSS) and was found to have the organ of Zuckerkandl PGL incidentally during surgery for gastrointestinal stromal tumor (GIST). aNovel mutation.
PGLs was a mean of 5.3 ± 3.8 cm. Analysis of the biochemical data reveals that nine patients had a noradrenergic phenotype, and three had both noradrenergic and dopaminergic phenotypes (Table 1). Four patients developed metastatic disease during follow-up, the time to metastases ranged from 2 to 19 years (6 ± 8.7). Sites of metastatic disease and multiple sites of disease are presented in Fig. 1. Surgical resection of the primary tumor was performed in 11/14 (79%) of the patients, while four patients received therapeutic 131I-MIBG, two received octreotide therapy, four received conventional radiation therapy, three patients with aggressive and metastatic disease additionally received chemotherapy.

Images obtained through imaging studies and surgical images demonstrating the organ of Zuckerkandl PGLs are shown in Figs 2 and 3. Pathology of a representative patient’s organ of Zuckerkandl PGL that is consistent with neuroendocrine tumor is presented in Fig. 4.

**Discussion**

The present study including 14 patients with PGLs of the organ of Zuckerkandl establishes for the first time an association of these tumors with SDHB and SDHD mutations. Our data also show that PGLs of the organ of Zuckerkandl are strongly associated with a noradrenergic phenotype and have an aggressive behavior, likely related to the SDHB mutational status. The identification of SDHx mutations in patients with the organ of Zuckerkandl PGLs has important implications for patient care and genetic screening of family members.

PGLs arise from sympathetic chromaffin tissue both in adrenal gland and outside of the adrenal gland in the abdomen or thorax, or alternatively originate from parasympathetic tissues in the head and neck (Benn et al. 2006). A particular grouping of PGLs, termed organ of Zuckerkandl PGLs, refer to a group of...
extra-adrenal chromaffin tissue situated between the origin of the inferior mesenteric artery and the bifurcation of the aorta (Ober 1983). These PGLs are remnants of the primitive sympathetic nervous system. The function of the organ of Zuckerkandl is unknown in humans; however, it is thought to act as a chemoreceptor in other species (Hollinshead 1940). Mutations in genes encoding the SDH subunits B, C, and D of mitochondrial complex II have been associated with PGL development (Baysal et al. 2000, Astuti et al. 2001, 2003, Gimenez-Roqueplo et al. 2003, Brouwers et al. 2006, Ghayee et al. 2009). While most head and neck PGLs are associated with SDHD gene mutations, PGLs derived from the sympathetic nervous system are often related to SDHB gene mutations. This is especially true for those deriving from extra-adrenal intra-abdominal lesions, which are frequently metastatic (Brouwers et al. 2006, Burnichon et al. 2009). Recently, mediastinal PGLs were also found to be strongly associated with mutations in SDHB gene (Ghayee et al. 2009).

While the majority of our patients had mutations in the SDHx genes, there are two important exceptions. One patient with primary adrenal pheochromocytoma as well as with organ of Zuckerkandl PGL who did not have a mutation in SDHx also had congenital polycythemia. She was also tested (data not shown) for a mutation of the gene encoding the prolyl hydroxylase domain 2 protein, but she was found to be negative (Ladroue et al. 2008). Another patient who presented with a GIST and was incidentally found to have an organ of Zuckerkandl PGL at the time of surgery was also not found to have SDHx mutation or deletion. Although most patients with CSS have SDHx mutations, up to 10% may harbor deletions that are not detectable by current screening methods (Carney & Stratakis 2002, Pasini et al. 2008).

Testing for SDH subunits is now recommended for all cases of pheochromocytomas and PGLs, and testing should be offered to first-degree relatives for cancer surveillance and early detection (Neumann et al. 2002, Amar et al. 2005, Benn & Robinson 2006, Jimenez et al. 2006, Prodanov et al. 2009). In addition, young patients with extra-adrenal pheochromocytomas should be tested for germline mutations of the von Hippel–Lindau (VHL) gene (Pacak et al. 2007, Boedeker et al. 2009). Germline mutations in the SDHD and SDHB genes should be considered a risk factor for PGLs of the organ of Zuckerkandl, and radiographic analysis of this area should be performed. However, exact surveillance recommendations for asymptomatic carriers of SDHx mutations may vary between institutions (Benn & Robinson 2006).

Clinical presentation of pheochromocytomas and PGLs is variable depending on functionality of tumor; 70–80% of PGLs of the organ of Zuckerkandl are clinically functional (Subramanian & Maker 2006).
Most extra-adrenal paraganglia as well as paraganglia in the setting of a SDHB mutation primarily secrete norepinephrine or norepinephrine and dopamine, as they lack phenylethanolamine N-methyltransferase, the enzyme responsible for the conversion of norepinephrine to epinephrine (Timmers et al. 2007). Our patient group is consistent with this finding in the predominance of noradrenergic phenotype. Interestingly, three of our patients had tumors with mixed secretion of both norepinephrine and dopamine, all of whom had SDHB mutations, consistent with previous studies linking this specific biochemical phenotype to the presence of SDHB mutations (Timmers et al. 2007). Surgical resection is the preferred treatment for organ of Zuckerkandl PGLs; 11/14 of our patients underwent resection; however, a subset of patients presented with metastatic disease that was not amenable to resection. Similar to what is known about other extra-adrenal pheochromocytomas, organ of Zuckerkandl PGLs have a higher rate of malignancy than adrenal pheochromocytomas (Altergott et al. 1985). A review of 135 cases of organ of Zuckerkandl PGLs found that 41% of these tumors were malignant based on the presence of metastases and local invasion, with the most common sites of metastatic disease including bone, liver, and lungs (Subramanian & Maker 2006). This finding is well supported by our data that shows that 86% of patients with organ of Zuckerkandl tumors had multiple sites of disease and/or metastatic disease.

We conclude that SDHB and SDHD mutations are indicators of possible organ of Zuckerkandl tumors and should lead to appropriate clinical studies and investigation of family members. This is also supported by our findings and previous findings that noradrenergic and dopaminergic phenotype in the same patient strongly suggest the presence of SDHB gene mutation that should be addressed in planned genetic testing. As organ of Zuckerkandl PGLs are linked to SDHx-associated disease, having a PGL in the organ of Zuckerkandl impacts the probability of an SDHB or D mutations and warrants mutation testing.
