Abstract

Macrophage migration inhibitory factor (MIF) is a pro-inflammatory cytokine that is over-expressed in several human neoplastic cells. When MIF binds its receptor (CD74) and co-receptor (CD44), it initiates signaling cascades that orchestrate cell proliferation and survival, and it can directly modulate the activity of AMPK. These activities indicate that MIF potentially regulates cell survival and metabolism. We found that MIF was primarily co-expressed with CD74 in 16 out of 23 papillary thyroid carcinoma (PTC) and in all the 27 available anaplastic thyroid carcinoma (ATC) biopsy samples. MIF and CD74 were co-expressed in TPC-1 and HTC-C3 cell lines. The selective MIF inhibitor, 4-iodo-6-phenylpyrimidine (4-IPP), blocked MIF/CD74 internalization, activated JNK, and dose-dependently inhibited proliferation inducing apoptosis and mitotic cell death. In two CD74-negative cell lines, NIM-1 and K1, 4-IPP treatment partially reduced proliferation. Coordinated MIF and CD74 expression appeared to confer in tumor cells the plasticity necessary to escape cell cycle regulation, metabolic changes, and stress conditions. MIF/CD74 signaling removal made cells susceptible to apoptosis and mitotic cell death. This finding suggests a possible avenue for targeting DNA endoreduplication, thus preventing the proliferation of therapy-resistant cell subpopulations. This study highlights MIF/CD74 axis as an important player in the biology of aggressive thyroid neoplasms.

Introduction

Macrophage migration inhibitory factor (MIF), a pleiotropic cytokine with inflammatory function and oxidoreductase activity, plays an essential role in both innate and adaptive immune responses. MIF antagonizes glucocorticoid immunosuppression, and it is implicated in the production of tumor necrosis factor α (TNF α) and nitric oxide (Bucala 2013). MIF also plays a role in cellular

responses to DNA damage and cell cycle regulation (Nemajero *et al.* 2007), and it affects glucose homeostasis through various pathways (Toso *et al.* 2008). MIF has been implicated in several disease conditions, including rheumatoid arthritis (Morand *et al.* 2006) sepsis (Calandra & Roger 2003), diabetes (Sánchez-Zamora & Rodríguez-Sosa 2014), and cancer (Candido & Hagemann 2013).

In cancer, MIF promotes growth, cell cycle progression, and angiogenesis. MIF signaling is mediated by interacting with CD74, a single-pass, type II membrane receptor, also known as the MHC class II chaperone invariant chain (Sanchez-Niño *et al.* 2013). MIF binding to the extracellular domain of CD74 stimulates rapid, sustained activation of ERK–MAP signaling (Leng *et al.* 2003), phosphatidylinositol-3/protein kinase B (PI3K/AKT) signaling (Lue *et al.* 2007), and Src signaling through CD44 recruitment (Shi *et al.* 2006). MIF binding to the CD74/CD44 complex regulates cell survival and proliferation by inhibiting apoptosis and activating prostaglandin E₂ production in a variety of cell types (Startlets *et al.* 2006). In some immune processes, MIF acts as a non-cognate ligand of chemokine receptors, CXCR2 and CXCR4. Biochemical evidence suggests that, upon MIF stimulation, these receptors may act as additional, signal-transducing CD74 co-receptors (Klasen *et al.* 2014).

Recent findings indicated that MIF binding to CD74 stimulated heart and muscle glucose uptake, and that the autocrine/paracrine effects of endogenous cardiac MIF contributed to AMP-activated protein kinase (AMPK) activation and glucose uptake during ischemia (Wang *et al.* 2014). Moreover, MIF can operate intracellularly in protein-protein interactions with proteins that modulate the intracellular redox state (Thiele & Bernhagen 2005) and with several key proteins that govern the cell cycle. MIF antagonizes Jab1-dependent cell-cycle control by regulating the Skp1-Cullin-1-F-box (SCF) ubiquitin E3 ligase complex, which coordinates ubiquitin-mediated destruction of two inhibitors of cyclin-dependent kinases, cyclins p21 and p27 (Fingerle-Rowson & Petrenko 2007). Additionally, through a mechanism not fully understood, MIF inhibition of Jab1 also negatively modulates the JNK-mediated stress response (Kleemann *et al.* 2000).

Papillary thyroid cancer outcomes are generally favorable, but up to 30% of patients relapse after an initial treatment with curative intent, and 15% die from the disease (Kloos 2005). Surgery and radioactive iodine therapy effectively treat the majority of cases. However, effective options for systemic therapy are limited in patients with advanced, unresectable, radioiodine-refractory thyroid cancer. Novel therapeutic approaches are required to treat anaplastic and poorly differentiated thyroid carcinoma, which are often resistant to current available therapies. Treatments for advanced thyroid cancer will require more insight into thyroid carcinogenesis (Kojic *et al.* 2011).

In this study, we show the elevated expression of MIF and CD74 in papillary and anaplastic thyroid cancer samples and cell lines. By *in vitro* experiments using cell lines we

observed that 4-iodo-6-phenylpyrimidine (4-IPP) perturbation of MIF/CD74 axis coincided with the loss of signaling pathways that regulate salvage pathways of endoreduplicated/tetraploid cells. A caveat of these effects is that MIF/CD74 positive cell lines were a mixture of diploid and tetraploid cells. Targeting tetraploid cancer cells is an important goal, particularly given the potential involvement of these cells in tumor progression, therapy resistance, and aneuploidy. Our data support that MIF/CD74 signaling pathway may represent a potential therapeutic target for patients with anaplastic thyroid carcinoma (ATC).

Materials and methods

Cell culture and drug treatment

The papillary thyroid carcinoma (PTC)-derived cell lines, TPC-1, NIM-1, K1, and B-CPAP were obtained from American Type Culture Collection (ATCC, Rockville, MD, USA). The ATC-derived cell line, HTC-C3 was obtained from Riken Gene Bank (RGB, Koyadai, Tsukuba Science City, Japan). Cell lines were authenticated by the Fragment Analysis Facility at Istituto Nazionale dei Tumori, Milan, Italy, with the StemElite ID System (Promega). The short tandem repeat (STR) DNA profile was matched to the original DNA profile in the cell line, as previously described (Schweppe *et al.* 2008). Cells were routinely tested for mycoplasma. TPC-1, NIM-1, B-CPAP and HTC-C3 cells were grown in DMEM (Gibco) supplemented with 10% fetal bovine serum (FBS; HyClone Laboratories, Logan, UT, USA) and 1 mM sodium pyruvate. K1 cells were grown in DMEM: Ham'sF12:MCDB (2:1:1) (Gibco) supplemented with 10% FBS (HyClone Laboratories). For cell treatments, 88.5 mM of 4-IPP (Calbiochem) in 100% DMSO was diluted directly in the cell culture medium to achieve the working concentrations. The final solvent concentration was <0.1% for all samples, including controls.

For immunochemistry, TPC-1 and NIM-1 cell lines were treated with the following antibodies: anti-CD74, anti-MIF (Abcam, Inc., Cambridge, UK), and an anti-mouse IgG1 (Sigma–Aldrich) as control. The antibodies were diluted directly in the cell culture medium to achieve the working concentrations. In all experiments, cell lines have been used at passage five and maintained in culture until the twentieth passage.

Proliferation assay and immunofluorescence

The sulforhodamine B (SRB) proliferation assay (Sigma–Aldrich) and immunofluorescence experiments were

performed as previously described (Caccia *et al.* 2010). PTC and ATC cells were stained with fluorescent phalloidin (Sigma–Aldrich) for visualizing the cytoskeleton, with diamidino-2-phenylindole (DAPI) (Biostatus Limited, Leicestershire, UK) as a nuclear marker, with anti- β -tubulin (Sigma–Aldrich) for visualizing microtubules organization and with anti-phospho-histone H3 (S10) (Abcam, Inc.) for visualizing histone H3. Slides were imaged with immunofluorescence microscopy (Eclipse E1000; Nikon Instruments, Inc., NY, USA).

FACS analysis

PTC cell lines (TPC-1 and K1) were seeded on 100-mm tissue culture plates, incubated for 18 h, then treated with drugs for 0, 12, 24, 48, or 72 h. Next, FACS analysis was performed as previously described (Caccia *et al.* 2010).

Sample preparation, SDS–PAGE, and immunoblotting

PTC and ATC cell lines (TPC-1, K1, NIM-1, B-CPAP and HTC-C3) were seeded at 12.5×10^4 cells/cm², cultured for 18 h, and exposed to drugs for the times indicated. Cell pellets were solubilized as previously described (Caccia *et al.* 2010). Normal, papillary and anaplastic frozen tissue samples (~50 mg) were homogenized and solubilized as previously described. Protein concentrations were determined with the bicinchoninic acid (BCA) assay (Bio-Rad Laboratories). Protein separation by electrophoresis (SDS–PAGE) and electroblotting were performed as previously described (Gorla *et al.* 2009) western blot quantifications were performed using Quantity one software (Bio-Rad).

Tissue specimens

Thyroid samples were collected at the Department of Pathology at Fondazione IRCCS Istituto Nazionale dei Tumori, Milano (INT). The PTCs ($n=23$) and ATCs ($n=27$) were classified according to WHO Classification (Delellis *et al.* 2004). The non-neoplastic thyroid tissues ($n=27$) were from patients with pathologies other than thyroid tumors. The study was performed in accordance with the Declaration of Helsinki Principles.

Immunohistochemistry

Immunohistochemistry was performed with 3- μ m, formalin-fixed, paraffin-embedded tissue sections. Tissues were stained with hematoxylin eosin or probed with

mouse MAB against CD74 (LN2; diluted 1:100; Abcam, Inc.) and against MIF (4E4; diluted 1:200; Abcam, Inc.). Immunohistochemistry was performed with an automated immunostainer (BenchMark Ultra, Ventana Medical Systems, Inc., Tucson, AZ, USA) according to the manufacturer's instructions.

Feulgen reaction

Feulgen reaction was performed with FEULGEN reaction for DNA kit (Bio-Optica Milano SpA, Milano, Italy) on 3- μ m frozen tissue sections derived from normal thyroid tissues, PTCs and ATCs sample tissues according to manufacturer's instructions.

siRNA transfection

TPC-1 cells were seeded at 3×10^4 cells/cm², cultured for 18 h, and transfected with siRNA against the MIF sequence, according to the siIMPORTER method (Upstate). After 72 h, the cells were lysed and lysates were analyzed by western blotting. The siRNA controls were siRNA non-targeting (NT) and siRNA mock.

MIF labeling and uptake experiments

Recombinant human MIF protein (rMIF, Cell Guidance Systems, Cambridge, UK) was conjugated with the AlexaFluor 546/488 dye with the Microscale Protein Labeling Kit (A30006; Invitrogen). PTC cell lines were seeded at 12.5×10^4 cells/cm² and cultured for 18 h. The medium was removed, and cells were washed twice with PBS to remove endogenous MIF. Alexa⁵⁴⁶MIF or Alexa⁴⁸⁸MIF (pre-treated overnight with 4-IPP or untreated) was added directly to fresh culture medium to achieve a final concentration of 400 ng/ml, and cells were cultured at 37 °C. After 0, 30, or 60 min, cells were washed, fixed in 4% paraformaldehyde, and stained with anti-CD74 (ImmunoTools, Friesoythe, Deutschland), anti-CD44 (Cell Signaling Technology, Inc., Boston, MA, USA), or anti-CXCR4 (Abcam, Inc.). DAPI stain (Biostatus Limited) was used as a nuclear marker. Slides were imaged with immunofluorescence microscopy (Eclipse E1000; Nikon Instruments, Inc.).

nLC–MS/MS analysis and isotope dilution mass spectrometry analysis

TPC-1 cells were treated with 50 or 100 μ M 4-IPP. After 24 h, proteins secreted in the medium (secretome) by

TPC-1 cells were collected and identified, as previously described (Caccia *et al.* 2011). Also, after 24 h, TPC-1 cells treated with 100 μ M 4-IPP were lysed; the lysate was analyzed by isotope dilution mass spectrometry, as previously described (Leoni *et al.* 2012).

Antibodies

The following antibodies were used for immunoblotting: anti-CD74, anti-MIF, anti-securin, anti-CXCR4, anti-phospho-histone H3 (S10) (Abcam, Inc.), anti-cyclin B1 (Santa Cruz Biotechnologies), anti-phospho-JNK (T183/Y182), anti-phospho-p38^{MAPK} (T180/Y182), anti-phospho-Akt (Ser 473), anti-Jab1, anti-cleavedPARP, anti-CD44, anti-phospho-AMPK α (T172), anti-AMPK α , anti-BCL2, anti-phospho-mTOR (S2448), anti-mTOR, anti-phospho-p70 S6 kinase (T389), anti-p70 S6 kinase, anti-cyclin D1, anti-ERK1/2 (Cell Signaling Technology, Inc.), anti-phospho-ERK1/2 (T183/Y185), anti- β -tubulin (Sigma–Aldrich).

Statistical and pathway analysis

Each experiment was performed at least three times. The statistical significance of the results was determined using Student's *t*-test. Data were considered significant when $P \leq 0.05$. Biological processes of significant proteins were analyzed with MetaCore (Thomson Reuters, Philadelphia, PA, USA). *P* values reflect the probability that one or more proteins might be detected by chance. Statistical significance was ascertained with a false discovery rate (FDR) threshold of <0.05 .

Results

CD74 was up-regulated in a large subset of PTC cells

CD74 and MIF expression patterns were investigated in 27 normal (including three cases of Hashimoto's thyroiditis), and 23 PTC tumor tissues with western blot analysis. PTC samples showed higher levels of CD74 than normal thyroid tissues (Fig. 1A). In addition, expression levels of the main MIF receptor, CD74, and a key MIF/CD74 downstream effector, cyclin-D1 were elevated in PTC samples compared to normal thyroid tissue (Fig. 1A). MIF and Jab1 protein levels were similar in PTC and normal tissues. Phospho-ERK (pERK) expression was variable among the different PTC samples. However, we noted that tumors with high levels of MIF and Jab1 exhibited low levels of pERK. Conversely, tumors with low Jab1 levels exhibited high levels of pERK (eg, PTC 3 and PTC 6 samples;

Fig. 1A). The most representative sections from normal (NT) and neoplastic thyroid tissues (PTC) (NT 3, NT 5, NT 7, PTC 6, PTC 9, PTC 11, and PTC 12) were immunostained for MIF and CD74 (Fig. 1B). Normal follicular cells exhibited strong perinuclear positivity for MIF, but endothelial cells and smooth muscle cells were MIF-negative. MIF was strongly expressed in all PTC samples tested and its staining pattern was mainly cytoplasmic (Fig. 1B).

CD74 immunostaining exhibited a weak cytoplasmic signal with a dot-like pattern in normal follicular epithelial cells. Scattered follicles showed stronger positivity. CD74 was also detected in endothelial cells, histiocytes, and lymphocytes when present. In some neoplastic tissues, CD74 staining was weak or moderate in 10–20% of tumor cells but, in other cases, staining was moderate in $>60\%$ of tumor cells. The staining pattern was always cytoplasmic and membranous (Fig. 1B).

Expression patterns of MIF and MIF-receptors in human PTC cell lines

MIF is expressed in thyroid tumors and normal thyroid tissues. The main MIF receptor, CD74, was also detected in a fraction (70%) of neoplastic tissues; CD74 was expressed in both epithelial and stromal compartments. This suggested that MIF and CD74 might play a functional role in conferring activities essential for tumor cell survival. Therefore, we assessed MIF protein levels in a panel of four PTC-derived cell lines, TPC-1, K1, NIM-1, and B-CPAP cells. In western blot analyses, we found that all four cell lines expressed high levels of MIF in both cell lysates and conditioned media (Fig. 2A). We also assessed the expression of MIF receptors, CD44, CXCR4, and CD74, and the intracellular binding partner, Jab1. Western blotting showed that high levels of CD44, CXCR4, and Jab1 were expressed in all four PTC-derived cell lines (Fig. 2A). However, although CD74 expression was strong in the TPC-1 cell line, it was nearly undetectable in the B-CPAP cell line, and it was not expressed in K1 or NIM-1 cells (Fig. 2A).

Extracellular MIF taken up by endocytosis co-localized with CD74

CD74 has been identified as the high-affinity binding protein for extracellular MIF. However, MIF-mediated signal transduction requires an interaction between CD74 and CD44, which involves the internalization of MIF via vesicle-mediated endocytosis (Kleemann *et al.* 2002). We investigated MIF-associated endosomal signaling mechanisms in TPC-1 and B-CPAP cell lines, which

Figure 1

CD74 is up-regulated in a large subset of PTCs. Immunoblotting analysis of the principal proteins in the MIF/CD74 pathway. (A) PTC homogenates showed high CD74 and cyclin-D1 protein expression compared to normal thyroid tissues. MIF, Jab1 and pERK expression was similar in PTC and normal thyroid tissues. Homogenates were resolved on 4–12% SDS–PAGE gels and immunoblotted with the indicated specific antibodies. Expression levels were normalized by comparing with β -tubulin. *The patient had Hashimoto thyroiditis. Western blot analysis were performed in triplicate.

(B) Immunohistochemical staining of normal (NT) and tumor (PTC) thyroid tissues with anti-MIF and anti-CD74 antibodies. Original magnifications are indicated in brackets, as follows: anti-MIF immunostaining: A, NT 5 (10 $\times$); B, NT 7 (10 $\times$); C, NT 3 (10 $\times$); D, NT 5 (20 $\times$); E, PTC 12 (10 $\times$); F, PTC 11 (20 $\times$); G, PTC 6 (10 $\times$); H, PTC 9 (20 $\times$). Anti-CD74 immunostaining: I, NT 5 (10 $\times$); L, NT 7 (10 $\times$); M, NT 5 (20 $\times$); N, NT 5 (40 $\times$); O, PTC 11 (10 $\times$); P, PTC 12 (10 $\times$); Q, PTC 9 (10 $\times$); R, PTC 11 (20 $\times$).

expressed high and low levels of CD74 respectively. Cells were incubated with human rMIF fluorescently labeled with AlexaFluor⁵⁴⁶ dye, which has been shown to be compatible with MIF biological activity (Kleemann *et al.* 2002). Cells were incubated with 400 ng/ml Alexa⁵⁴⁶MIF for 30 or 60 min at 37 °C. After 30 min, rMIF was internalized efficiently in vesicle-like structures that were clearly detectable in the TPC-1 cell line (Fig. 2B). In the B-CPAP cell line, we observed a phenomenon comparable to that observed in TPC-1 cells (Fig. 2B), but rMIF internalization was nearly undetected. To determine whether rMIF internalization was mediated by CD74, we treated TPC-1 and B-CPAP cells with rMIF and immunostained with fluorochrome-conjugated anti-CD74 antibodies. In TPC-1 cells, we observed strong co-localization of rMIF and CD74 in vesicles-like structures (Fig. 2C). We only observed a slight co-localization signal in B-CPAP cells (Fig. 2C). Next, we analyzed whether CD74 co-localized with CD44

in TPC-1 and B-CPAP cell lines, as previously described (Sanchez-Niño *et al.* 2013). The results showed a clear co-localization of CD74 and CD44 in TPC-1 cells, but only a modest co-localization in the B-CPAP cell line (Fig. 2D). Then, we incubated CD74-negative NIM-1 and K1 cell lines with Alexa⁴⁸⁸MIF (400 ng/ml) for 30 or 60 min at 37 °C. A negligible number of vesicle-like endocytotic structures were observed at both time points (Fig. 2E). Of note, rMIF appeared to localize in the nucleus or cytoplasm. In NIM-1 and K1 cells incubated with anti-CD44, Alexa⁴⁸⁸MIF co-localized weakly with the CD44 signal (Fig. 2F and G). In some immune processes, MIF acts as a non-cognate ligand of the CXCR4 chemokine receptor; because NIM-1 and K1 cell lines were CXCR4-positive, we also assessed whether Alexa⁴⁸⁸MIF co-localized with anti-CXCR4 antibodies. However, co-localization was very faint, which suggested that, in NIM-1 and K1 cell lines (Fig. 2F and G), MIF may signal through receptor-independent pathways.

Figure 2

MIF is strongly expressed and released by human papillary thyroid cell lines. Endogenous MIF protein was measured in the lysates and conditioned media of human papillary thyroid carcinoma (PTC)-derived cell lines. In addition, endogenous CD74, CD44, CXCR4, and Jab1 protein levels were measured in PTC-derived cell line lysates. (A) Representative immunoblots of cell lysates and conditioned medium from the indicated cell lines. For all immunoblots, β -tubulin was used as loading control. Western blots analysis were performed in triplicate. (B) Extracellular MIF was endocytosed in vesicle-like structures via CD74. Cells were incubated with 400 ng/ml Alexa⁵⁴⁶MIF for 30 and 60 min at 37 °C. Negligible staining at 0 min indicated that the signal was intracellular (not non-specific cell surface staining). At 30 min, MIF was efficiently internalized in clearly detectable, vesicle-like structures (white arrows). (C) TPC-1 and B-CPAP cells treated with recombinant Alexa⁵⁴⁶MIF were immunostained for CD74. MIF and CD74 were strongly co-localized in TPC-1 cells and less strongly co-localized

in B-CPAP cells. (D) TPC-1 and B-CPAP cells stained with anti-CD74 and anti-CD44 antibodies. CD74 and CD44 were strongly co-localized in TPC-1 cells, which suggested formation of a receptor complex. B-CPAP showed moderate CD74-CD44 co-localization. (E) Cells were incubated with 400 ng/ml Alexa⁴⁸⁸MIF for 30 and 60 min at 37 °C. Fluorescent signals were negligible at 30 min and low at 60 min. MIF was internalized less efficiently through a non-specific, non-receptor-mediated mechanism (white arrows). (F) NIM-1 and K1 cells treated with recombinant Alexa⁴⁸⁸MIF were immunostained to detect CXCR4 receptors. MIF and CXCR4 were weakly co-localized. (G) NIM-1 and K1 cells treated with recombinant Alexa⁴⁸⁸MIF were immunostained to detect CD44. MIF co-localization with CD44 was negligible. The figures show representative data of a representative experiment. All immunofluorescence experiments were performed in triplicate. Magnifications were 60 $\times$ and 100 $\times$. Scale bar = 50 μ m.

These results were consistent with previous findings that MIF internalization was mediated by CD74/CD44 dependent and independent mechanisms.

Changes in cell proliferation following MIF inhibition

To investigate the molecular and cellular mechanisms associated with the targeting of MIF-dependent signaling, TPC-1, B-CPAP, NIM-1, and K1 cell lines were treated with the MIF inhibitor, 4-IPP at the following concentrations already reported in the literature: 10, 25, 50 and 100 μ M

(Winner *et al.* 2008). We confirmed the specific association between MIF and 4-IPP under our conditions with matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS). After incubating rMIF and 4-IPP for 3 h at room temperature, we observed a mass shift of $\sim$ 282 Da, which corresponded to the molecular mass of 4-IPP. Thus, 4-IPP could effectively recognize its target (Supplementary Figure 1A, see section on supplementary data given at the end of this article). We evaluated the cellular and molecular effects of MIF inhibition by treating TPC-1, NIM-1, B-CPAP, and

K1 cells with various concentrations of 4-IPP (10, 25, 50, and 100 μ M). Twenty-four hours after treatment, the TPC-1 cells were rounded and exhibited highly refractive bodies, reminiscent of repair processes and/or cell death (Fig. 3A). Rhodamine-labeled phalloidin staining showed that 4-IPP induced a significant decrease in F-actin-containing stress fibers, and the actin filaments exhibited a dense, non-polar arrangement (Fig. 3B). B-CPAP, NIM-1, and K1 cells treated with 4-IPP showed no relevant changes in morphology.

A SRB analysis indicated that, after 72 h of 25 μ M 4-IPP, TPC-1 cell proliferation decreased by up to 60% ($P < 0.001$; Fig. 3C, a). At 50 and 100 μ M 4-IPP, after 72 h, TPC-1

proliferation was completely blocked and cell death occurred. B-CPAP cells showed similar effects with 4-IPP, but to lesser extent (Fig. 3C, b). In NIM-1 and K1 cell lines, low 4-IPP concentrations (10 and 25 μ M) caused negligible effects; 4-IPP at 50 μ M, after 72 h, reduced cell proliferation by up to 25–30%, but 100 μ M 4-IPP caused a strong decrease in cell proliferation (Fig. 3C, c and d). Finally, we tested whether MIF and CD74 neutralization could impact proliferation in CD74-positive cell lines. Anti-MIF antibody, anti-CD74 antibody, or a control IgG1 was administrated to TPC-1 cells at 2, 4, or 8 μ g/ml for 0, 24, 48, and 72 h. The results clearly showed that MIF or CD74 immunodepletion strongly inhibited TPC-1 proliferation (Fig. 3D).

Figure 3

Effect of MIF inhibition on cell proliferation and growth. (A) Micrographs of TPC-1, B-CPAP, NIM-1, and K1 cells before and after drug treatments. 4-IPP treatment induced a marked morphological change in TPC-1 cells, resulting in a smaller, contracted appearance and decreased cell spreading. 4-IPP had no effect on the morphology of B-CPAP, NIM-1, and K1 cell lines. (B) Immunofluorescence microscopy of TPC-1 cells before and after treatment with 50 μ M 4-IPP. Cells were stained with phalloidin to visualize actin. The figure shows data of a representative experiment. All immunofluorescence experiments were performed in triplicate. Magnifications: 60 $\times$ and 100 $\times$. Scale bars=50 μ m. (C) Proliferation curves of TPC-1, B-CPAP, NIM-1, and K1 cells treated with 4-IPP. After 72 h of 25 μ M 4-IPP, cell proliferation was significantly ($P < 0.001$) reduced in TPC-1 cells (60%), (a) reduced in B-CPAP cells (30%), and (b) unaffected in NIM-1 and (c) K1 cells (d). After 72 h at

50 and 100 μ M 4-IPP, (a) TPC-1 cells did not grow at all; (b) B-CPAP cell proliferation decreased by 80–90% ($P < 0.001$); (c) NIM-1 cell proliferation was reduced by 20 and 60% respectively ($P < 0.001$); and (d) K1 cell proliferation was reduced by 40 and 90%, respectively ($P < 0.001$). Representative growth curves from one experiment are shown. Each point represents the mean of eight independent replicates $\pm$ s.d. (D) TPC-1 cells were labeled with specific anti-MIF and anti-CD74 antibodies. After 72 h, TPC-1 growth was reduced by 70% (2 μ g/ml anti-MIF) to 90% (4 and 8 μ g/ml anti-MIF) ($P < 0.001$). After 72 h, 2 μ g/ml anti-CD74 antibody reduced TPC-1 cell proliferation by 10–15%, but at 4 and 8 μ g/ml, cell proliferation was reduced by 80 to 90% ($P < 0.001$). Representative growth curves from one experiment are shown. Each point represents the mean of eight independent replicates $\pm$ s.d. All proliferation assays were performed in triplicate.

AMPK is modulated in response to 4-IPP in CD74-positive TPC1 cell line

To clarify MIF-induced signaling in tumor thyroid cells, we analyzed MIF signaling in CD74-positive and CD74-negative cell lines. Cells underwent siRNA-mediated MIF silencing and 4-IPP treatment. Silencing MIF in CD74-positive TPC-1 cells reduced ERK phosphorylation, the main downstream effect of the MIF/CD74 axis (Fig. 4B). Treatment with 100 μ M 4-IPP switched off ERK phosphorylation in TPC-1 cells almost completely, though the level of protein expression was unmodified. Also, Akt and Jab1 phosphorylation was abrogated (Fig. 4A) and cyclin-D1 expression levels were down-regulated (Fig. 4A). With 50 μ M 4-IPP, p38 and JNK phosphorylation levels were strongly increased in TPC-1 cells (Fig. 4A). In B-CPAP cells, 10, 25, and 50 μ M 4-IPP slightly reduced ERK phosphorylation. However, at 100 μ M, 4-IPP increased ERK and p38 phosphorylation and decreased cyclin-D1 expression (Fig. 4A). In CD74-negative K1 and NIM-1 cell lines, 4-IPP treatment did not significantly affect cyclin-D1 expression

(Fig. 4A). However, ERK-related p44 isoform expression and p38 phosphorylation were slightly increased (Fig. 4A). We next tested whether MIF/CD74 signaling activated AMPK in TPC-1 cells. MIF inhibition with 10, 25, 50, and 100 μ M 4-IPP strongly decreased AMPK phosphorylation. At 100 μ M 4-IPP, both mTOR phosphorylation and ribosomal protein S6 expression were reduced (Fig. 4C). However, 4-IPP treatment in B-CPAP, K1, and NIM-1 cell lines did not alter phosphorylated AMPK or mTOR expression (Fig. 4C). This result suggested that the MIF/CD74 signaling axis was involved in modulating the AMPK/mTOR pathway.

Cell cycle effects of MIF inhibition

To investigate the impact of MIF inhibition on cell cycle and cell death, we compared two PTC cell lines: TPC-1 (CD74-positive) and K1 (CD74-negative). TPC-1 and K1 cells were treated with different concentrations of 4-IPP (50 and 100 μ M) for 0, 12, 24, and 72 h. FACS analysis of K1 cells stained with propidium iodide indicated that 4-IPP

Figure 4

Time- and concentration-dependent molecular effects of MIF inhibition. (A) Immunoblots of the principal proteins involved in the CD74/MIF pathway. TPC-1, B-CPAP, NIM-1, and K1 cells were untreated or treated with 10, 25, 50, and 100 μ M 4-IPP for 24 h. Then, lysates were resolved by 4–12% SDS–PAGE and immunoblotted with specific antibodies as indicated. Expression levels were normalized to β -tubulin expression. (B) Western blot analysis of MIF and pERK1/2 expression in TPC-1 cells treated with MIF

siRNA for 24 h. Results were normalized with respect to total ERK protein ($P > 0.005$). (C) Immunoblots of the principal proteins involved in the AMP kinase (AMPK) pathway. TPC-1, B-CPAP, NIM-1, and K1 cells were untreated or treated with 10, 25, 50, 100 μ M 4-IPP for 24 h. Cell lysates were resolved by 3–8% SDS–PAGE and immunoblotted with specific antibodies as indicated. Expression levels were normalized to β -tubulin expression. Western blot analysis was performed in triplicate.

Figure 5

Cell cycle effects of MIF inhibition. (A) Cell cycle analysis of TPC-1 and K1 cells exposed to 4-IPP. Representative flow cytometric profile of cell cycles in TPC-1 and K1 cells, analyzed with propidium iodide staining. Analysis was performed with the CellQuest program (Becton Dickinson). Treatments and the percentage of cells in the difference phase of cell cycle are

indicated. The figure show data from a representative experiment and all experiments were performed in triplicate. (B) Bar-graph represents the relative percentage of TPC-1 and K1 cells in various cell cycle phases over time in the presence of 50 or 100 μ M 4-IPP. The values represent the average of three independent experiments.

only slightly impacted the cell cycle (Fig. 5A). Cell cycle analysis of untreated TPC-1 cells at 0, 12, 24, and 72 h of culture revealed a mixture of diploid and tetraploid cells. Tetraploidization was present in 10–35% of the cells. However, at 48 h, they were completely depolyploidized and had re-entered the mitotic cycle. When TPC-1 cells were treated with 50 μ M 4-IPP for 48 h, a fraction of cells (27.44%) maintained tetraploidy. However, after 72 h, a similar fraction of cells (26.85%) became apoptotic (Fig. 5A and B). Treatment of TPC-1 cells with 100 μ M 4-IPP for 24 h caused 11.88% apoptosis, an increase in S-phase (66.04%) diploid cells, and an accumulation of cells with 4N DNA content (60.49%). We tentatively attributed the latter finding to arrest in the G2/M transition (Fig. 5A and B). Longer incubations led to a large increase in the number of arrested cells; 20.20% were apoptotic, and the remaining cells had 2N DNA contents. After 48 h, the TPC1 cells undergoing apoptosis increased, and cells accumulated in the G1 phase (46.90%) and the S-phase (40.13%); after

72 h, cells accumulated in the G2/M-phase (38.78%) and the G1-phase (48.79%). Microscopic analysis of treated cells indicated a high number of cells with marked nuclear abnormalities, including multinucleation in all cell lines indicating abnormal mitosis with failed cytokinesis.

Taken together, these data clearly indicated that 4-IPP induced multinucleated cells and some of the nuclei show morphologic features of apoptotic cell death consistent with mitotic catastrophe in a dose- and time-dependent manner. To support the notion that MIF inhibition could induce these effects in TPC-1 cells, we compared the nuclei and microtubule cytoskeletons to those of K1 cells with immunofluorescence. TPC-1 and K1 cells were treated with 50 and 100 μ M 4-IPP for 24, 48, and 72 h. Before treatment, both cell lines showed typical radial, diffuse microtubules (green β -tubulin, Fig. 6A) and normally shaped nuclei (blue; Fig. 6A).

The 4-IPP treatment did not change the morphology, microtubule organization, or nuclei in K1 cells.

Figure 6

MIF inhibition disrupts microtubule networks in CD74-positive cell line. (A) Coverslips with TPC-1 (CD74⁺) and K1 (CD74⁻) cells were incubated with 50 or 100 μ M 4-IPP or with DMSO (vehicle) for 24, 48, and 72 h. Then cells were fixed and stained with anti- β -tubulin antibody (green) to visualize microtubules and with DAPI (blue) to visualize cell nuclei. Fluorescence micrographs show untreated TPC-1 cells with typical radial microtubule arrays. After 24, 48, and 72 h of 4-IPP treatment, microtubule organization was disrupted in TPC-1 cells. The formation of giant, multinucleated cells was characteristic of mitotic catastrophe. In contrast,

K1 cells treated with 4-IPP showed typical radial microtubule arrays and normal nuclei organization. The figures show data of a representative experiment. All immunofluorescence experiments were performed in triplicate. Magnification: 60 $\times$. Scale bar: 50 μ M. (B) Western blot analysis of cleaved PARP, BCL-2, cyclin-B1, securin and phospho-histone-H3 (S10) in TPC-1 and K1 cell lines treated with 10, 25, 50, or 100 μ M 4-IPP for 24 h. Expression levels were normalized to β -tubulin expression. Western blot analysis were performed in triplicate.

Figure 7

MIF inhibition produces proteomic and metabolic changes. (A) Proteins in conditioned medium were assessed for function before and after 4-IPP treatment. The *P* value from the hypergeometric test, generated by Metacore, represents the enrichment of certain proteins; those included in the processing network, 'Proteolysis_ECM remodeling', for untreated TPC-1 cells (orange line), or those included in the metabolic network, 'Carbohydrate metabolism_Glycolysis, Gluconeogenesis and glucose

transport', for 4-IPP treated TPC-1 cells (blue line). The FDR value is also reported (B). The table shows the values of the metabolites analyzed after TPC-1 treatment with 4-IPP at 100 μM . The results were expressed as $\text{ng}/\text{mg}_{\text{proteins}}$ and were normalized to the value of total proteins present in each sample. Data and values represent the average of three independent experiments.

In contrast, 50 and 100 μM 4-IPP disrupted the microtubule networks in TPC-1 cells after 24 h. Furthermore, these cells exhibited micro- and multinucleation, similar to previous descriptions of mitotic catastrophe

(blue-stained nuclei, Fig. 6A). The same results were obtained with 100 μM 4-IPP after 48 and 72 h. TPC-1 cells treated with 100 μM 4-IPP accumulated cyclin-B1 (Fig. 6B), and they maintained securin expression.

These findings supported the notion that 4-IPP suppressed a cell-cycle checkpoint and caused a deficit in chromosome separation. In contrast, no changes were observed in cyclin-B1 expression in K1 cells (Fig. 6B). The 4-IPP (at 100 μ M after 24 h) treatment also caused a cleavage in PARP and reduced the expression of the anti-apoptotic protein, BCL-2 in TPC-1 cells; these factors led to favorable conditions for apoptosis (Fig. 6B). In contrast, 4-IPP did not activate PARP or reduce BCL-2 expression in K1 cells. Taken together, our results suggested that inhibiting the MIF/CD74 axis led to TPC-1 cell death, probably through a mitotic catastrophe. As shown in Fig. 5A and B, and consistent with previous cell proliferation studies (Fig. 3C), we found that 100 μ M 4-IPP induced a population of multinucleate cells at 72 h in K1 cells. Thus, 4-IPP apparently led to G2/M arrest and multinucleation.

These results showed that 4-IPP treatment in CD74-negative cells resulted in a dose- and a time-dependent G2/M arrest and multinucleation.

MIF inhibition produces proteomic and metabolic changes

Proteins secreted in the culture medium (secretome) represent activities, properties, and functional activities of tumor cells (Caccia *et al.* 2011). We analyzed the proteins secreted by TPC-1 cells in the presence or absence of MIF inhibition to identify key mediators of the 4-IPP effects produced in TPC-1 cells. We profiled the secretome of TPC-1 cells subjected to 24 h of 50 and 100 μ M 4-IPP with LC-MS/MS and label-free quantitative proteomics approaches. As expected, many released proteins were

mediators of critical cellular functions that were modulated by MIF (Fig. 7A). Specifically, we found that MIF inhibition was associated with the modified release of proteins involved in glycolysis/gluconeogenesis (Fig. 7A). We also performed isotope-dilution gas chromatography mass spectrometry (GC-MS) analysis (Leoni *et al.* 2012) of cellular lysates after 24 h 4-IPP treatment. We found that lactate, pyruvate, and malate were elevated and citrate and fumarate were reduced (Fig. 7B). We hypothesized that 4-IPP caused a partial inefficiency in the mitochondrial tricarboxylic acid cycle (suggested by reduced citrate and fumarate, Fig. 7B), possibly due to a reduction in oxidative phosphorylation efficiency, which reduced ATP synthesis. The conversion of pyruvate into lactate can regenerate NAD and increase the activity of malic dehydrogenase (i.e., we found elevations in malate). With impaired mitochondrial function, glycolysis may be increased to maintain adequate ATP production, when ATP consumption is reduced. The 4-IPP treated cells also showed reductions in cholesterol, fatty acids, and cholesterol synthesis (Fig. 7B). These findings were consistent with the hypothesis that 4-IPP suppressed mitochondrial activity and activated glycolysis and lactate production. Thus, 4-IPP may cause changes in cellular ATP production.

ATC sensitivity to 4-IPP inhibitor

To further evaluate the relevance of the MIF/CD74 signaling axis in undifferentiated/anaplastic carcinoma presenting marked nuclear pleomorphism, we determined the expression of MIF/CD74 signaling components

Figure 8

Anaplastic thyroid carcinoma sensitivity to 4-IPP inhibitor. (A) Scatter plots showing densitometric scan values of western blot band of normal thyroid, PTC and ATC samples using antibodies against CD74, MIF, pERK and β -tubulin. The values, normalized to β -tubulin and expressed as fold changes, refer to 27 normal thyroid tissues, 23 PTC and 27 ATC tissues. (B) Hematoxylin eosin and immunohistochemical staining of two representative ATC tissues (A and B) with anti-CD74 antibody. Original magnifications are indicated in brackets, as follows: hematoxylin eosin staining: A, ATC sample 1 (10 $\times$); B, ATC sample 2 (10 $\times$). Anti-CD74 immunostaining: A1, ATC sample 1 (10 $\times$); B1, ATC sample 2 (10 $\times$); A2, ATC tissue one (20 $\times$); B2, ATC tissue two (20 $\times$); A3, ATC tissue one (40 $\times$); B3, ATC tissue two (40 $\times$). (C) Feulgen staining of normal thyroid tissue (A), PTC tissue (B) and ATC tissue (C). The figure shows the most representative tissue section for each group of tissue samples (normal tissue, PTC and ATC). Magnification: 100 $\times$ oil. Scale bar: 100 μ M. (D) Proliferation curves of HTC-C3 cells treated with 4-IPP. After 24 h of 10, 25, 50, and 100 μ M 4-IPP, cell proliferation was significantly ($P < 0.001$) reduced in HTC-C3 cells (70–80%). After 72 h at 25, 50, and 100 μ M HTC-C3 cells did not grow at all. At 10 μ M of 4-IPP cell proliferation was dramatically reduced in HTC-C3 cell line (70%; $P < 0.001$). Representative growth curves from one experiment

are shown. SRB assay was performed in triplicate. Each point represents the mean of eight independent replicates $\pm$ s.d. (E) Western blot analysis of CD74, MIF, pERK, ERK1/2, pAkt, pJNK, phosphor-p38, p53, cleaved PARP and phosphor-histone H3 in HTC-C3 cell extracts. HTC-C3 cells were untreated or treated with 10, 25, 50, and 100 μ M 4-IPP for 24 h; then, lysates were resolved by 4–12% SDS-PAGE and immunoblotted with specific antibodies as indicated. Expression levels were normalized to β -tubulin expression. Western blot analysis were performed in triplicate. (F) Coverslips with HTC-C3 (CD74-positive) cells were incubated with 2, 5, 10 or 25 μ M 4-IPP or with DMSO (vehicle) for 72 h. Then cells were fixed and stained with β -tubulin antibody (green) to visualize microtubules and with DAPI (blue) to visualize cell nuclei. Fluorescence micrographs show untreated HTC-C3 cells with typical radial microtubule arrays. In contrast, treated cells frequently developed multiple nuclei, including micronuclei. Microtubule organization was disrupted and, as well, cells were also much larger than untreated HTC-C3 cells. These features were characteristic of mitotic catastrophe. The figures show representative data from a representative experiment. All immunofluorescence experiments were performed in triplicate. Magnification: 60 $\times$. Scale bar: 100 μ M.

in 27 ATC tissues by western blot and of CD74 in representative sections of 27 patient samples by IHC staining. Results showed that in all tumors, the malignant cells strongly expressed CD74 (Fig. 8B). Some tumors also showed positivity in the stromal components (Fig. 8B). Quantification of the western blot data for CD74, MIF, and pERK proteins demonstrated a strong increase in the expression levels of CD74 protein in the ATC samples when compared with PTC and normal thyroid samples (Fig. 8A). Nuclear pleomorphism in ATC samples was ascertained by performing the Feulgen reaction (Fig. 8C).

We assessed whether 4-IPP could inhibit the MIF/CD74 signaling axis by determining its effects on cell proliferation and the expression of targets in a HTC-C3 cell line positive for both CD74 and MIF. Sensitivity to 4-IPP was observed and the cytotoxic efficacy of 4-IPP in treated cells was assessed at different concentrations and times. As illustrated in Fig. 8D, the HTC-C3 cells were highly sensitive in the range of ~10–100 μ M of inhibitor, demonstrating that 4-IPP could reduce the proliferation rate of this anaplastic cell line. To better understand the molecular mechanisms of cell death induced through 4-IPP treatment, we conducted western blot analysis of treated HTC-C3 cells. As shown in Fig. 8E, treatment led to an increase in JNK and phospho-p38 activity in a dose-dependent manner.

The 4-IPP-treated cells were also much larger than untreated cells (Fig. 8F). Most treated cells developed multiple nuclei, and in some cases, we observed the formation of micronuclei, including misfolding microtubules. To evaluate whether 4-IPP induces cell cycle arrest at mitosis, we stained cells with anti-phospho-histone H3 (serine 10), a mitotic marker, and DAPI, a DNA-specific dye (Supplementary Figure 1B). In response to 4-IPP treatment (2.5–25 μ M), cells showed a time- and concentration-dependent increase in positivity. Western blot analysis of protein expression levels of phospho-histone H3 showed an increased response to the 4-IPP treatment (Fig. 8E). Treated cells displayed a significant increase in cleaved PARP (cPARP) whereas total β -tubulin levels remained the same. Overall, the results suggested that 4-IPP could lead to a cell cycle arrest in the G2/M phase, triggering arrest-mediated apoptotic cell death.

Discussion

This study was the first to show that MIF was abundantly expressed in both normal and cancerous thyroid tissues, though with different subcellular localizations. In 70%

of PTC and 100% of ATC cases, neoplastic tissues showed expression of CD74 in cells other than those in the lymphocyte population.

To investigate the functional significance of MIF/CD74 signaling, we inhibited MIF activity with 4-IPP in CD74-positive and CD74-negative cell lines. Our results indicated that i) CD74 was essential for obtaining significant cell proliferation inhibition and inducing cell death; ii) untreated TPC-1 cells showed an AMPK and ERK activation that was sensitive to 4-IPP whereas JNK phosphorylation was barely detected and spontaneous endoreduplicative and apoptotic processes coexisted; iii) at 24 h of culture of TPC-1 cells, a large fraction of polyploid cells had escaped death and initiated a de-polyploidization process producing viable descendants, probably through reduction division or alternative mechanisms; iv) 4-IPP treatment dose-dependently inhibited proliferation by blocking the G2/M transition and induced TPC-1 cells to exhibit the morphological features of mitotic cell death; v) concomitantly with treatments, we observed a strong reduction in AKT, ERK, and AMPK phosphorylation, increased Jab1, and the appearance of a peak of JNK and p38 phosphorylation; and vi) 4-IPP effects were recapitulated in the anaplastic (CD74-positive) thyroid HTC-C3 cell line.

Treatment with 4-IPP produced consequences similar to those seen with isothiocyanates, a group of plant-based chemicals present in cruciferous vegetables that are part of the human diet. These compounds are thought to prevent cancer and principally target MIF in intact cells (Higdon *et al.* 2007). As noted, similar effects were also obtained using an Ebselen compound (Supplementary Figure 1E and F).

Results with the 4-IPP treatments indicate that the MIF/CD74 axis supports the proliferative and metabolic pathways. These functions have been previously reported in other studies. MIF stimulates heart muscle glucose uptake, and the autocrine/paracrine effects of endogenous cardiac MIF contribute to AMPK activation and glucose uptake during ischemia (Qi *et al.* 2009). Thus, AMPK is considered a type of cardioprotective stress kinase (Russell *et al.* 2004), and the action of MIF modulation of AMPK is beneficial during ischemia.

We found that a failure in MIF/CD74 signaling reduced AMPK function. In parallel, cell cycle arrest and mitotic cell death were observed. Our metabolomic analysis produced results that were consistent with the hypothesis that 4-IPP may cause reduced oxidative phosphorylation efficiency, decreasing ATP synthesis. We believe that in the TPC-1 cell line, the MIF/CD74

axis may produce a higher energy state of the cell (glucose uptake) by accelerating either ATP production or consumption. AMPK could also contribute to mitochondrial function, stimulating mitochondrial biogenesis via phosphorylation of the PGC1 co-activator and regulating expression of mitochondrial genes (Li *et al.* 2011).

Vazquez-Martin *et al.* reported a physical interplay between active AMPK with mitotic regulators in the centrosome and midbody. Thanks to these relationships, AMPK coordinates sensing of energy resources and the fundamental biological process of genome division during mitosis and cytokinesis. The same authors analyzed the phenotypes that resulted from pharmacologically induced overactivation of AMPK and observed a dramatic reorganization compatible with multinucleation, with the proportion of polyploid cells reaching >30% of the total population (Vazquez-Martin *et al.* 2009). We think that MIF/CD74 axis might reproduce the effects of a pharmacologically induced overactivation of AMPK, which is likely responsible for supporting an energetic infrastructure underlying an aberrant mitotic/cytokinetic machinery.

Suppression of MIF/CD74 signaling not only blocks this bioenergetic resource but also increases oxidative stress, activating JNK and the stress response and producing cell death. Of interest, Yun *et al.* (2009) have shown how glucose deprivation activates JNK and apoptotic signals in DU145 cells. Reactive oxygen species production may be crucial in linking glucose deprivation induced by the AMPK and JNK signaling pathways. In agreement with previously reported results (Bech-Otschir *et al.* 2002), our findings show that a lack of MIF provoked recovery of Jab1, which could contribute to the activation of JNK.

The p53 expression in the TPC-1 cell line did not change with 4-IPP treatment (Supplementary Figure 1D). Recent evidence suggests that apoptosis and senescence are repressed in some tetraploid cells through epigenetic silencing of p53 target genes (Zheng *et al.* 2012). Indeed, MIF inhibits p53-dependent gene expression and suppresses apoptosis associated with p53 activation and redox stress (Lue *et al.* 2007). Nevertheless, our results are consistent with the notion that p53 is not required for mitotic cell death (Toh *et al.* 2010). Overall, the current findings indicate that JNK triggers a death response and that the MIF/CD74 axis is crucial in this process.

The analysis of 27 clinical specimens indicated a high level of CD74 and MIF expression and expression of downstream targets. ATC cells are naturally resistant to irradiation and chemotherapy. Because of their proficient

ability to repair treatment-induced DNA damage during G2 cell-cycle arrest, unrepaired DNA damage accumulates in cells that prematurely enter mitosis, producing pleomorphic, undifferentiated, highly aggressive giant cell carcinoma cells. Via induction of JNK activity, 4-IPP proved to be extensively cytotoxic in HTC-C3 cells. In fact, a parallel increase in PARP cleavage was observed along with a strong increase in phospho-histone H3 signal intensity, which is a hallmark of oxidant-induced DNA damage and cell death (Tikoo *et al.* 2001). These results suggest cell type-dependent apoptosis induction by oxidative stress.

Our results indicate the importance of the MIF/CD74 axis in supporting tumor polyploidy. 4-IPP holds promise as a new anti-polyploid therapeutic drug, which could potentially be used to target polyploid tumor cells in thyroid cancer patients. This work demonstrates that the MIF/CD74 axis is required for continued cell proliferation of TPC-1 and HTC-C3 cells and that it activates AMPK even as JNK is inhibited, predisposing cells to endoreduplication. Furthermore, the cell cycle functions of MIF/CD74 axis provide important opportunities for future studies of how it conveys its anti-apoptotic activity. MIF/CD74 axis may be differentially regulated in normal vs cancer cells. If so, MIF/CD74 axis could prove to be a promising target for ATC treatment.

The current literature also supports a role for MIF in the development of obesity, chronic inflammation, and insulin resistance. As therapies targeting the MIF/CD74 pathway reach clinical development, new opportunities also may arise for the treatment of cancer. ATC remains an intractable disease with poor outcome, and this tumor type requires new therapeutic strategies. Novel therapies that specifically target polyploidization provide a new approach to inducing sustained remission and increasing overall survival. However, little is known about the side-effects induced by blocking endoreduplication. Continued advances in our understanding of the process of polyploidization and how it differs from the proliferative cell cycle will provide additional targets for therapeutic intervention.
